The reaction of a cautious criticism to such a demonstration seems to have taken two different directions. There has been a tendency, on one hand, to exclude an agent from the group of viruses as soon as the microscope could demonstrate it with some certainty. Many have for years thus excluded the agent transmitting the pleuro-pneumonia of cattle, though the status of this organism has been compromised even more by the success of its cultivation on artificial media. Visibility seems to have rendered doubtful the position of the Rickettsia group of infections, and, if the test is logically applied, the process of exclusion can scarcely stop before the agents transmitting psittacosis, fowl-pox, infectious ectromelia, and even vaccinia and variola, have been removed from the group of viruses into that of visible organisms.

In discussing the biological nature of viruses as a whole, however, we can scarcely begin by accepting an artificial and shifting limitation of that kind. The real task before us, rather, is to discuss to what extent the evidence of these recent developments, which appear to show that some of the agents, known hitherto as viruses, consist of very minute organisms, can safely be applied to other viruses which are still beyond the range of resolution. Do these also consist of organisms still more minute, or are any of them unorganised? Another line of criticism, sound in itself, while not excluding from the virus group these agents for which microscopic visibility has been claimed, demands more evidence that the minute bodies seen or photographed are really the infective agent, and not merely products of a perverted metabolism which its presence engenders.

It is obvious that complete evidence of identity cannot be obtained until a virus has been artificially cultivated in an optically homogeneous medium. Meanwhile it is a question of the strength of a presumption, on which opinions may legitimately differ. Let us recognise that the evidence is not perfect, but beware of a merely sterilising scepticism. I suspect that the attitude of some critics is coloured by past history of the search for viruses and especially by that part of it concerned with the curious objects known as 'inclusion bodies', which are readily demonstrated with relatively low powers of the microscope, in the cells of animals and plants infected with certain viruses. From the earlier and admittedly hasty tendency to identify them as infective protozoa, opinion seems to have swung too quickly to the opposite extreme, of dismissing them as mere products of the infected cell. It is so comparatively simple, in some cases, to separate these bodies, that it is surprising that so few efforts have been made to test their infectivity. However, the power of such a body to convey at least one virus infection has been demonstrated; and since they have further been shown, in several cases, to consist of a structureless matrix packed with bodies looking like minute organisms, the burden of proof in other cases seems to me, for the moment, to rest on those who suggest that they consist wholly of material precipitated by the altered metabolism due to the infection.

The physical evidence, obtained by filtration through porous fabrics and colloidal membranes, and by measuring rates of diffusion, is, of course, purely concerned with the size of the units of infective material, and must be taken in conjunction with the evidence provided by the microscope. The crude qualitative distinction between the filterable and non-filterable agents of infection has long since ceased to have any real meaning. There is no natural limit of filterability. A filter can be made to stop or to pass particles of any required size. It is now realised that the only proper use of a filter in this connexion is to give a quantitative measure of the maximum size of the particles which pass it. Evidence from failure to pass must always be subject to correction for the effects of electrostatic attraction and fixation by adsorption on the fabric of the filter. A large amount of filtration evidence has, further, been vitiated by reliance on determinations of the *average* pore size of the filter. In dealing with an infective agent, the test for the presence of which depends on its propagation under suitable conditions, it is obviously the maximal pore size which is chiefly significant.

For these reasons a good deal of the evidence showing that certain viruses can be detected in the filtrates, obtained with filters which will not allow hæmoglobin to pass in perceptible quantities, must be regarded at least with suspicion. Dr. Elford has recently succeeded in preparing filter-membranes of much greater uniformity, with a small range of pore-diameters. His measurements, with these, of the sizes of the particles of different viruses, show a range approaching the dimensions of the smallest recognised bacteria, on one hand, and falling as low, in the case of the virus of foot-and-mouth disease, as about three or four times the size of the hæmoglobin molecule; the latter being given not only by filtration-data, but also by other physico-chemical measurements, such as those obtained by Svedberg with the ultra-centrifuge. It should be noted, as illustrating the difficulties of the problem and the uncertain meaning of some of the data, that Elford has regularly found a bacteriophage to be stopped by a membrane which allows the foot-and-mouth virus to pass; while, on the other hand, recent determinations of the rate of diffusion of bacteriophage, made by Bronfenbrenner, put the diameter of its particles at 0·6 of a millimicron, that is, only about one-fifth of the accepted dimensions of the hæmoglobin molecule. If we accepted such an estimate, we should be obliged to conclude, I think, not merely that the bacteriophage is unorganised, but that its molecules are something much simpler than those of a high-molecular protein. It has even been suggested, though on very imperfect evidence, that it may be a moderately complex carbohydrate. Are we, then, to suppose that the foot-and-mouth virus is a similarly unorganised and relatively simple substance ? It is difficult to do so, in view of the series of other agents, all conforming in many aspects of their behaviour to the classical type of the foot-and-mouth virus, and yet showing a range of dimensions up to that at which their units are apparently becoming clearly visible by modern microscopical methods.

It will be clear, indeed, that, if we accept the lowest estimates for the size of the units of some viruses, such as the bacteriophage and the agents transmitting some plant diseases, we cannot by analogy apply the conception of their nature, thus presented, to viruses consisting of organisms which are ceasing to be even ultramicroscopic ; and we should be led to doubt the identity with the virus of the bodies which the microscope reveals. If, on the other hand, we regard the still invisible viruses, by analogy with those already seen, as consisting of even much smaller organisms, we can only do so by rejecting the conclusions drawn from some of the physical evidence. It is, of course, possible that some of the agents called viruses are organisms and others relatively simple pathogenic principles in solution ; but to assume at this stage such a fundamental difference, among members of a group having so many properties in common, would be to shirk the difficulty.

The third negative characteristic of a virus, namely, its failure to propagate itself, except in the presence of living cells which it infects, may obviously again provide an unstable boundary, shifting with the advance of our knowledge and skill. We may regard it as not only possible, but even likely, that methods will be found for cultivating artificially, on lifeless media, some of those viruses at least which have the appearance of minute organisms. It would be playing with nomenclature to let inclusion in the virus group depend on continued failure in this direction. On the other hand, the dimensions assigned to the units of some viruses, representing them as equal in size to mere fractions of a protein molecule, might well make one hesitate to credit them with the power of active self-multiplication. Experience provides no analogy for the growth of such a substance by self-synthesis from the constituents of a lifeless medium ; the energetics of such a process might present an awkward problem. To account for the multiplication of such a substance at all, even in cells infected by it, we should be driven, I think, to the hypothesis which has been freely used to account for the propagation of bacteriophage, on one hand, and of typical viruses like that of herpes, on the other ; namely, that the presence of the virus in a cell constrains the metabolism of the cell to produce more.

Bordet has used the reproduction of thrombin by the clotting of the blood as an analogy for the suggested reproduction of bacteriophage in this manner. Another, and perhaps closer, analogy might be found in recent evidence that a culture of pneumococcus, deprived of its type-specific carbohydrate complex, can be made to take up the carbohydrate characteristic of another type, and then to reproduce itself indefinitely with this new, artificially imposed specificity. The response of the cells of the animal body to even a single contact with a foreign protein, by the altered metabolism producing immunity, and often persistent for the lifetime of the individual, may suggest another parallel ; but here the protective type of the reaction is in direct contrast to the supposed regeneration by the cells of the poison which killed them.

Boycott, again, has emphasised the difficulty of drawing a sharp line of distinction between the action of normal cell-constituents, which promote cell-proliferation for normal repair of an injury, and the virus transmitting a malignant tumour, or that causing foot-and-mouth disease. I do not myself find it easy, on general biological grounds, to accept this idea of a cell having its metabolism thus immediately diverted to producing the agent of its own destruction, or abnormal stimulation. It is almost the direct opposite of the immunity reaction, which is not absent, but peculiarly effective in the response of the body to many viruses. It is difficult, again, to imagine that a virus like rabies could be permanently excluded from a country if it had such an autogenous origin. The phenomena of immunity to a virus, and of closely specific immunity to different strains of the same virus, are peculiarly difficult to interpret on these lines.

This conception, however, of the reproduction of a virus by the perverted metabolism of the infected cell has been strongly supported by Doerr, in explanation of the phenomena of herpes. There are individuals in whom the epidermal cells have acquired a tendency to become affected by an herpetic eruption, in response to various kinds of systemic or local injury. From the lesions so developed, an agent having the typical properties of a virus can be obtained, capable of reproducing the disease by inoculation into individuals, even of other species, such as the rabbit, and exciting, when appropriately injected, the production of an antiserum specifically antagonising the herpes infection. Such phenomena have a special interest for our discussion, in that they can be almost equally well explained by the two rival conceptions. One regards the herpes virus as a distinct ultramicroscopic organism, and the person liable to attack as a carrier, in whom the virus can be awakened to pathogenic activity and multiplication by injuries weakening the normal resistance of his cells to invasion. The other regards it as a pathogenic principle produced by cells in response to injury, and awakening other cells to further production when transmitted to them.

This forms a good example of the central difficulty in dealing with the group of agents at present classed together as viruses. They seem to form a series ; but we do not know whether the series is real and continuous, or whether it is formed merely by the accidental association, through a certain similarity in effects, and through common characteristics of a largely negative kind, of agents of at least two fundamentally different kinds. If we approach the series from one end, and watch the successive conquests of microscopical technique, or if we consider the phenomena of immunity over the whole series, we are tempted to assume that all the viruses will ultimately be revealed as independent organisms. If we approach from the other end, or consider analogies from other examples of a transmissible alteration of metabolism, we may be tempted to doubt the significance of the evidence provided by the microscope, and to conclude that all viruses are unorganised, autogenous, toxic principles. If we take the cautious attitude of supposing that both are right, and that viruses belonging to both these radically different types exist, where are we going to draw the line? Is the test to be one of unit dimension? If so, what is the lower limit of the size of an organism? Are we to suppose that inclusion bodies can only be produced by viruses which are independent organisms? And if so, does this conclusion also apply to the 'X' bodies associated with the infection of plant cells by certain viruses?

If we try to form an estimate of the lower limit of size compatible with organisation, I think we should remember that particles which we measure by filters of known porosity, or by photomicrographs, need not be assumed to represent the virus organisms in an actively vegetative condition. They may well be minute structures, adapted to preserve the virus during transmission to cells in which it can resume vegetative life. Attempts to demonstrate an oxidative metabolism in extracts containing such a virus, separated from the cells in which it can grow and multiply, and to base conclusions as to the non-living nature of the virus on failure to detect such activity, must surely be regarded as premature.

Our evidence of the vitality of its particles is, as yet, entirely due to their behaviour after transmission. They may accordingly contain protein, lipoid and other molecules in a state of such dense aggregation that comparisons of their size with that of the heavily hydrated molecules of a protein in colloidal solution may well give a misleading idea of their complexity.

Apart from their known function as the agents transmitting many of the best known among the acute infections, it is impossible, to anyone having even a slight knowledge of the recent developments which began with the work of Rous and Murphy, to doubt that in the advance of knowledge concerning the nature of the viruses in general lies the brightest hope of finding a clue to the dark secret of the malignant tumours. In unravelling what is still such a tangle of contradictions, the animal biologist needs all the help that can be given by concurrent study of the analogous phenomena in plants.

Eels and Conger Eels of the North Atlantic.

By Prof. Johannes Schmidt.

In the course of the Danish investigations on the life-histories of the fresh-water eels (1904–1931) important data about the congers have been obtained. I hope it will be possible some time to give a more detailed picture of the history and distribution of the fresh-water eels and congers of the various oceans. Referring to my earlier publications,[1-8] I propose here to deal with the relation between the European and the American conger, which is generally referred to the same species as the European one. The investigation is mainly based upon a study of the larvæ and their distribution.

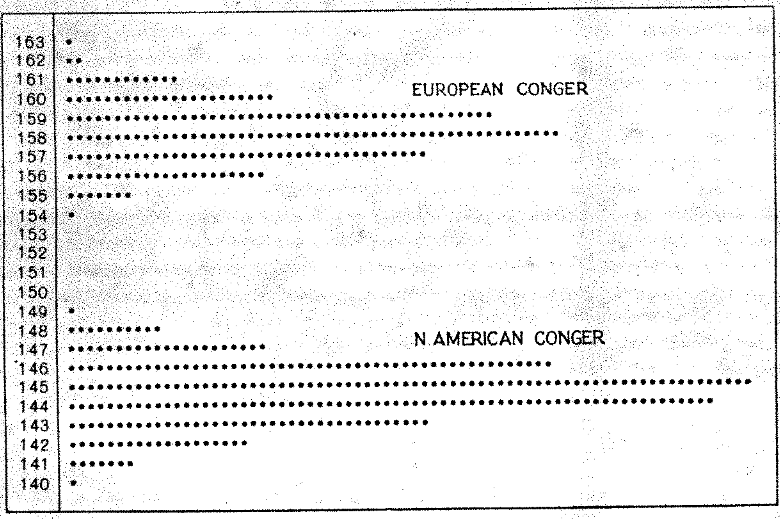

Fig. 1.—European and North American Conger (*Conger vulgaris* and *Conger oceanicus*). Number of myomeres in larvæ: *Conger vulgaris* (top graph), average of 201 specimens, 158·16; *Conger oceanicus* (lower graph), average of 288 specimens, 144·63. (Countings by Miss Esther Hansen.)

In the North Atlantic area, we obtained about 2500 larvæ belonging to the genus *Conger s. str.* By counting the myomeres we found that the material falls into two distinctly separate groups (Fig. 1). In the former, the number of myomeres varies between 154 and 163 with an average of 158·16, in the latter between 140 and 149 with an average of 144·63. So there is no overlapping of the two groups.

On marking the distribution of the larvæ of the two groups upon a chart, we find that the larvæ with the high myomere number occupy quite another and a much larger area than those with the smaller number. As shown by the charts (Figs. 2 and 3), the distribution is much like the one I have found in the case of the larvæ of the European and the American fresh-water eel respectively. Similarly, there is in both cases an overlapping of the areas.

We have determined the number of vertebræ in several hundred adolescent and adult specimens of the European conger (*Conger vulgaris*) and have found values between 153 and 161 (average between 157 and 158), which corresponds well with the above-mentioned values of myomeres in the group of larvæ with the higher number, the number of myomeres of the larvæ being a little higher than the number of vertebræ of the adult fish. This fact also holds good of the fresh-water eels and other murænoids.

As to the number of vertebræ in adult specimens of congers from North America, my material is much smaller than that for the European conger. Through the kindness of the United States Bureau of Fisheries, however, I received in 1922 four adult specimens originating from Woods Hole, Mass. A determination of their number of vertebræ gave the following figures: 143, 144, 144, 145, which is in complete agreement with the values of the group of larvæ with the smaller number.

In the circumstances, it is clear that the American conger is a species differing from the European one, and that it ought to be given a specific name. For want of types, I have applied for advice to American colleagues, namely, Prof. H. B. Bigelow and Mr. A. E. Parr, who think that the name used by Mitchell (*Jour. Ac. Nat. Sci. Phila.*, p. 407; 1818), namely, *Anguilla oceanica*, should be chosen. The fish in question being stated by Mitchell to occur "off New York", there is scarcely any doubt that he really had before him the American species with the smaller number of vertebræ. So we name the North American species *Conger oceanicus* as distinct from the European *Conger vulgaris*. However, I wish to direct attention to the fact that the name does not apply to the conger occurring in South America (Argentine), which by our investigations has proved to be different from the North American species.

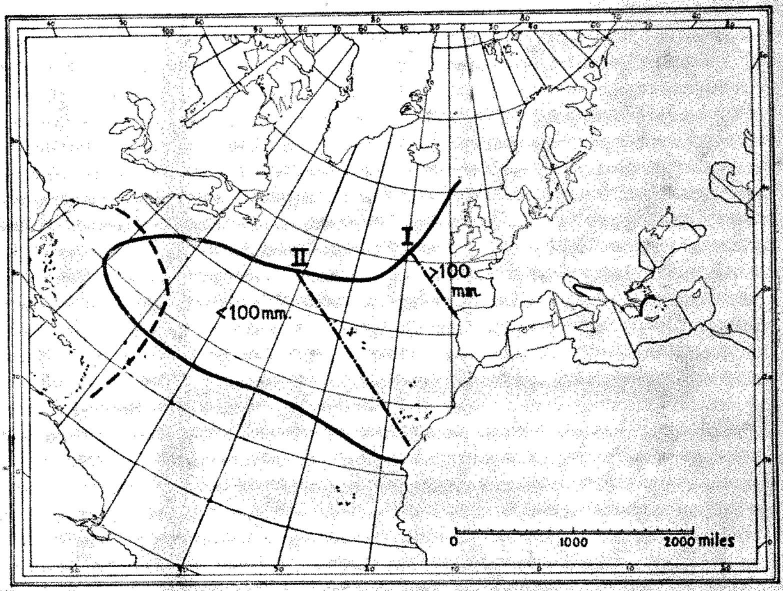

Fig. 2.—Distribution of unmetamorphosed larvæ of the European and North American species of congers (*Conger vulgaris* and *Conger oceanicus*). *Conger vulgaris*: East of line I all larvæ were more than 100 mm. long, west of line II all were less than 100 mm. in length, according to Danish investigations, 1904–1931. The American species indicated by *broken*, the European by *unbroken* curves. In contrast to the fresh-water eel, *Conger vulgaris* breeds in the Mediterranean and in the Eastern Atlantic.

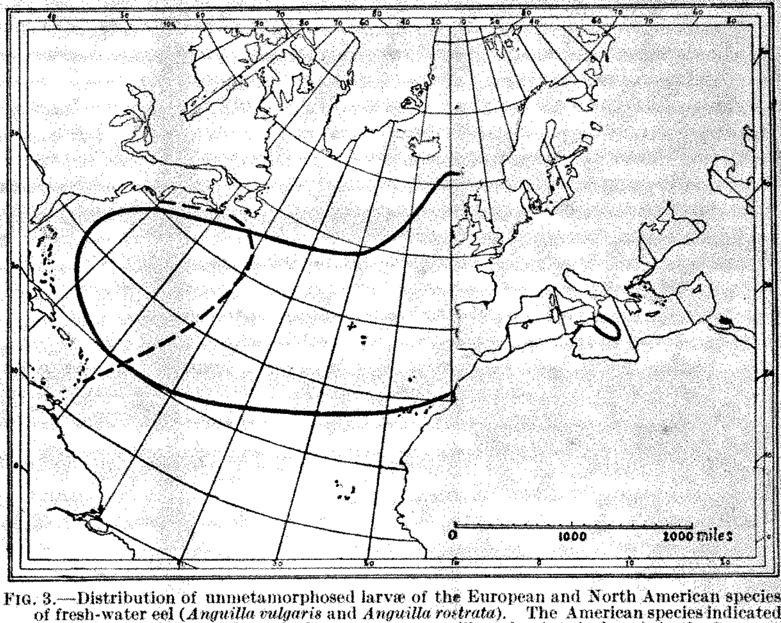

Fig. 3.—Distribution of unmetamorphosed larvæ of the European and North American species of fresh-water eel (*Anguilla vulgaris* and *Anguilla rostrata*). The American species indicated by *broken*, the European by *unbroken* curves. *Anguilla vulgaris* only breeds in the Sargasso Sea west of long. 50° W.

The distribution of *Conger oceanicus* is not nearly so wide as that of *Conger vulgaris*. We know that it occurs off the Atlantic coast of the United States, but we know little more. In the West Indies we have found quite tiny larvæ, a fact that permits us to conclude that here is the breeding place of the species. The appearance of these tiny larvæ agrees with the corresponding stages of development of *Conger vulgaris* described and pictured by me in 1912[4] and 1913.[6] The tiny stages, however, which Eigenmann (1902) hatched from pelagic eggs taken by the schooner *Grampus* south of Nantucket lightship, do not belong to *Conger* but to an *Ophichthys* or a closely related form, a fact to which I have already directed attention.[5]

I have already mentioned that there is a striking agreement between the distribution of the larvæ of the two *Conger* species and those of the two *Anguilla* species. It is especially interesting to compare the two European species, *Conger vulgaris* and *Anguilla vulgaris*, which, as shown by the maps (Figs. 2 and 3), are both distributed over a zone across the North Atlantic and the Mediterranean, a distance of about a quarter of the circumference of the globe. But while the fresh-water eel breeds only in the western Atlantic, from which place its larvæ, increasing in age and size, spread towards the north-east and the east over an area similar to the one taken up by the conger larvæ, matters are different as to the conger. For our investigations have shown that the European conger must have breeding places along the whole extent of the area from the Sargasso Sea to Egypt, because throughout this extent—always over great oceanic depths—we have found tiny larvæ, only 10 mm. in length.

The full-grown larvæ measure about 140–160 mm. in length. If we make a closer examination of the distribution of the larvæ of *Conger vulgaris* according to size, we find :

1. In the south-eastern part of the larvæ area, that is, from the Azores and eastwards between about lat. 30° and 40° N. to Gibraltar and onwards through the Mediterranean to Egypt, all sizes of larvæ from tiny to full-grown ones were found. This fact shows that we are dealing here with local conger populations.

2. From Cape Finisterre a line has been drawn on the map (Fig. 2) in a north-westerly direction (I) ; north of this line, that is, in the north-eastern part of the larvæ area, only older larvæ more than 100 mm. in length have been found. From this fact we may conclude that the conger populations of north-western and northern Europe, including the British Isles, are *not* of local origin, but originate from more distant regions of the Atlantic situated to the south and west.

3. From a point a little south of the Canary Islands a line has been drawn in a north-westerly direction passing a little west of the Azores and limiting the western part of the larvæ area (II). West of this line, that is, in the Sargasso Sea, we only found tiny (10 mm. in length) or half-grown larvæ, but none attaining a length of 100 mm. As the adolescent conger lives in shallow water, these larvæ must be the offspring of conger populations that have undertaken very long migrations to the breeding places. The origin of the *Conger vulgaris* breeding in the Sargasso Sea cannot be determined for certain at present. Since the tiny larvæ of *Conger vulgaris* occur in the Sargasso Sea together with the tiny larvæ of our European eel, and the larvæ, like those of the eel, increase in size from this place towards the north and north-east, I think it very probable that they migrate along the same routes to north-western and northern Europe, and that they are the offspring of the conger populations living there.

I can sum up as follows : it is a common feature of the eels and conger eels of the North Atlantic that both genera have an eastern (European) and a western (American) species, *Anguilla vulgaris* and *Conger vulgaris*, and *Anguilla rostrata* and *Conger oceanicus*, respectively. Both the eastern species have a higher number of vertebræ and a far wider distribution of the larvæ than the two western species. (Fig. 1.)

The adolescent European eel and European conger have, in the main, the same distribution, and this also holds good of their larvæ, when no account is taken of the age (size) of the latter. (Figs. 2 and 3.)

The European eel breeds in the western Atlantic and only there, in a limited area of the Sargasso Sea. The European conger has a much wider breeding area, as it breeds in the Mediterranean, in the eastern Atlantic between the Azores and Gibraltar, and in the west Atlantic (the Sargasso Sea).

So *Conger vulgaris* is not a biological unity like the fresh-water eel. It comprises different populations with different breeding places, breeding time, and migratory tendencies.

The Clerk Maxwell Centenary Celebrations.

THE University of Cambridge celebrated, on Oct. 1–2, the centenary of the birth of the first Cavendish professor of experimental physics, James Clerk Maxwell.

On Sept. 30, before the celebrations opened in Cambridge, memorial tablets to Faraday and Maxwell were unveiled in Westminster Abbey. The tablets are of the same size as that which marks Kelvin's resting-place, and they lie on the opposite side of the Newton floor-slab. There could be no more appropriate site. The short service was conducted by the Dean, and was attended by about four hundred members and delegates from the Royal Institution, delegates of the Maxwell celebration, and members of the University of Cambridge. The Master of Trinity unveiled the memorial, and in a short address emphasised the links between Faraday and Maxwell and their claims to such memorials.

The celebrations opened in Cambridge on Oct. 1, with the old Maxwell wing of the Cavendish Laboratory as its headquarters. About eighty official delegates had been nominated by the principal academies and learned societies of the world and by the home universities. Capt. J. Wedderburn Maxwell represented Maxwell's family, and there were present also some fifty guests, including at least twelve of those who had worked with Maxwell or sat at his lectures in the first days of the Cavendish Laboratory and many of those who have since helped to build up the school of experimental physics in Cambridge. A luncheon to the official delegates was given by the newly appointed Vice-Chancellor, the Master of Corpus, who in an introductory speech said that he counted himself fortunate in having this amongst the first of his new duties. The toast of the delegates, proposed by Lord Rutherford, was replied to by the Marchese Marconi and also by Prof. Max Planck, who said:

> "Maxwell's centenary is indeed a festive day—a day of honour for the physicists of all countries. In his personality we see not only the erudite savant mastering every domain of physics, but also the imaginative artist, who, like no other, knew how harmoniously to combine the separate material of investigation and thus to further its development. It is pre-eminently with Maxwell that this interweaving of sober intellectual activity with artistic intuition plays a particularly characteristic part.
>
> "In physics, intuition is a peculiar thing. Nowadays it has somewhat fallen into discredit, having really recently done a deal of harm: first in the province of relativity, where the seemingly evident conception of the simultaneousness of two events occurring in different places proved a gross delusion; then again in the province of the quantum theory, where it has proved absolutely impossible with the common forms of intuition completely to grasp the connexions between corpuscular and undulatory motion.
>
> "And yet those are wrong who wholly reject intuitions by asserting that theoretical physics is only concerned in the mathematical working out of the results of measurements. For he who quite forgoes tentative flights of imagination will never be struck by a new idea which can be made fruitful for experiments. Yet a careful distinction must be made between the operations of the intellect and those of fancy. Here Maxwell sets us a classic example. His theory of electrodynamics was originally founded on quite special ideas of the mechanical nature of the ether, in accordance with the fact that in his time the mechanical conception of Nature was considered nearly a matter of course, having received strong support through the discovery of the principle of conservation of energy. But after, by the aid of such mechanical notions, Maxwell had found his electromagnetic differential equations and had recognised the extent of their efficiency, he did not hesitate in pushing aside as a negligible accessory the mechanical interpretations of the differential equations, in order to make them independent and to give his theory its pure and sublime shape. Perhaps this most clearly characterises Maxwell's physical manner of thinking.
>
> "Thus to-day, when we are beset by more difficult problems, Clerk Maxwell can still teach us a good deal, and it is with the expression of sincere thanks and warm wishes that we greet the home of his activities: the University of Cambridge and particularly the Cavendish Laboratory."

After this impressive opening, the Vice-Chancellor and delegates proceeded in procession to the Senate House, where, after the welcome and presentation of delegates, the Master of Trinity delivered the memorial lecture, dealing first with Maxwell's life and personality and finally with his work. This address forms the first of the essays in the commemoration volume which has been published by the University Press.

After the ceremony in the Senate House, the guests were entertained by the Master and Fellows of Peterhouse, the college where Maxwell spent his first days in Cambridge. In the evening the reception given by the Master and Fellows of St. John's College filled the hall and combination room with a brilliant assembly.

Three of the main scientific addresses were given in the Arts School on the morning of Oct. 2. Prof. Planck's address on "The Influence of Maxwell on Theoretical Physics in Germany" will remain long in the memory of those present. Sir Joseph Larmor charmed the assembly with personal reminiscences of the celebrities who formed the scientific environment of Maxwell; he told in particular of a visit from Ludwig Boltzmann, who through misfortune had arrived penniless and without luggage in Cambridge, in search of models which he was sure Maxwell must have made to illustrate his electrodynamic field theory, and which he hoped to find in the lumber of the Cavendish Laboratory. After this, Prof. Niels Bohr gave an address on the influence of Maxwell's work on modern theoretical physics.

In the afternoon, under the presidency of Sir Richard Glazebrook, Sir James Jeans gave an address on Maxwell's methods, and Dr. William Garnett, the first demonstrator in the Cavendish Laboratory, related many new and delightful Maxwell stories. Some of his address may be quoted:

> "Perhaps to see Maxwell at his best was to see him at play. Few things could give him more pleasure than a new toy, whether designed by himself or anyone else, provided it showed some ingenuity in its design or construction; and to exhibit these toys to his friends at home in the evenings was a great delight. Maxwell's improved Zoetrope with its concave lenses and his real image stereoscope afforded much interest to visitors, but perhaps his favourite toys on these occasions were the flying butterflies with their revolving antennæ which he made to fly about the drawing-room at Scroops Terrace.
>
> "But if one looks for Maxwell's most characteristic feature, it is to be found in his sympathy with and love for every creature. Though very fond of country life, he would never hunt or shoot. In Cambridge and in London he nursed friends who were seriously ill, at the cost of much time taken from his work. During his last two years his work at the laboratory was greatly interrupted by the illness of Mrs. Maxwell, in whose room he would frequently sit all night. It is an interesting speculation whether, if his time had not been occupied by his wife's serious illness and the Cavendish papers, he would not have followed up his electromagnetic theory and experimentally produced long electric waves.
>
> "It was during the visit of the comet in 1874, when unfortunately the comet's tail was a subject of general conversation, that Maxwell's terrier developed a great fondness for running after his own tail, and though anyone could start him, no one but Maxwell could stop him until he was weary. Maxwell's method of dealing with the case was, by a movement of the hand, to induce the dog to revolve in the opposite direction and after a few turns to reverse him again, and to continue these reversals, reducing the number of revolutions for each, until like a balance wheel on a hair spring with the maintaining power withdrawn, by slow decaying oscillations the body came to rest.
>
> "I have been asked what Maxwell did when he wanted an experimental test of a theory and had not thought of one, or when a piece of apparatus behaved quite unexpectedly. According to his own statement

he 'dreamt over it properly', which he considered 'the best method of resolving difficulties of a particular kind which may be found out especially by the laws of association'."

Sir Ambrose Fleming spoke of his work at the laboratory during the last few years of Maxwell's life, and of Maxwell's lectures, attended only by three students. He presented to the laboratory the notes he took of Maxwell's last lectures. He thought it strange that Maxwell never lectured or spoke of his theory of electromagnetic waves. He had never heard any proposal for an experiment on electromagnetic radiation, and although there is in existence a letter from Maxwell to Garnett where he promises to write down for Fleming "a scheme for a radiating wire experiment", one is driven by the absence of any later development to conclude that this referred to the thermal radiation for the oil-cooled coils which were then being used for the B.A. experiments.

After Sir Oliver Lodge had wound up the addresses with an account of the development of wireless from Maxwell's equations to Marconi and the B.B.C., the proceedings were transferred to the Cavendish Laboratory, where, in the old rooms designed so carefully by Maxwell, were laid out for the first time since Maxwell's death the treasures which were bequeathed by Mrs. Maxwell.

The laboratory can count itself fortunate in Maxwell's characteristic of saving everything of interest from his toys, manuscripts, and apparatus. In one group were assembled the relics of his childhood and adolescence. The models of the regular solids made at the age of thirteen showed Maxwell's early geometrical interests; the strained pieces of glass and gelatine used in his early investigations on the optical properties of elastic solids when placed in the polariser showed the now familiar coloured strain figures, which could be compared with the same figures sketched out by Maxwell eighty years ago. The improved form of Zoetrope referred to by Dr. Garnett, with its clearly executed drawings of vortex rings in motion, and the drawings of more elaborate operations, in which his imagination was aided by the clear brush of Jemima Wedderburn, proved a great attraction. There was also his real image stereoscope which he constructed for the teaching and study of solid geometry, and the ophthalmoscope which he used for the study of the eyes of his friends.

In the next group could be seen the development of Maxwell's scientific interests; the colour-top with its sectors of different colours which he constructed whilst a graduate of Trinity College in 1854, and which was used to establish his colour equations and for the investigation of colour blindness; here also was the more perfect instrument of his last years in Aberdeen—the colour-box with its slits and prisms for combining different components of white light in any desired proportion. To illustrate his work on the dynamics of rigid bodies were three models of his dynamical top; the original wooden top used to entertain and mystify his undergraduate friends in Trinity College and the more perfect instrument of his Aberdeen days with its screws for the adjustment of the principal moments of inertia and devices for showing the motion of the instantaneous axis of rotation. One of the important applications of this top has been to show the connexion of the figure of the earth with a periodic variation in latitude. As a reminder of Maxwell's first excursion into statistical theory was shown the model of Saturn's rings constructed to illustrate two of the possible methods of propagation of waves amongst the particles of the rings; by it stood the original oscillating disc apparatus used for the measurements on the viscosity of gases which were carried out in his King's College days in his home in Kensington. There was also the small note-book with its record of swings and 'log decs.', and the triumphant letter to Tait announcing the independence of viscosity and pressure.

The activities of Maxwell as a member of the British Association Committee on Electrical Standards were fully illustrated by the spinning coil lent by the Science Museum to its old home, the apparatus used for the determination of the ratio of the units by balancing the electrostatic attraction of two discs against the electromagnetic repulsion of two coils, and the great B.A. electrodynamometer constructed in 1867 and used later by Lord Rayleigh for the determination of the ampere.

Most interesting of all, perhaps, were the manuscripts and letters of Maxwell. The delegacy of King's College, London, had kindly lent three of the small note-books in which Maxwell used to write down his examination questions, and in one of which are the first chapter headings of the "Electricity and Magnetism". Practically the whole of the manuscript of the first edition of the "Electricity and Magnetism" is in the possession of the laboratory, and various parts were exhibited, together with Maxwell's copy of the first edition. Here also were the manuscripts of his later papers, the note-books of his undergraduate days, and the notes of his lectures taken by Sir Ambrose Fleming. With the original plans of the Cavendish laboratory was a letter to Thomson asking for advice and giving his idea of what a laboratory should contain:

> "A place on the ground floor with solid foundations for things requiring to be steady. Access to the roof for atmospheric electricity. A place with good ventilation to set up Grove or Bunsen's batteries without sending fumes into the apparatus.
>
> "A good clock in a quiet place founded on masonry, electric connexion from this to other clocks to be used in the experiments, and from here connexion to machines for making sparks, marks on paper, etc.
>
> "A well-constructed oven, heated by gas to get up a uniform high temperature in large things.
>
> "A gas engine (if we can get it) to drive apparatus; if not, the University men in good training in four relays of two, or two relays of four, according to the nature of the experiment.
>
> "We should get from the B.A. some of their apparatus for the Standards Committee. In particular, the spinning coil and the great electrodynamometer."

Here also were letters to Tait announcing the discovery of the law of distribution of radiation and the famous catechisms to Thomson "concerning demons".

If one sought evidence for the unchanging perversity of scientific writers, there was Maxwell's letter written in October 1876:

> "How vile are they who quote newspapers, journals, and translations by number of vol. and page, instead of the year of grace, as if one should refer to the standard No. 16240 instead of Oct. 10, 1876. Lockyer always alters a reference to NATURE for Sept. 7, 1876, into vol. ?, p. ?, as if all promoters of natural knowledge counted everything from the epoch when NATURE first began."

Most interesting pictorial records of Maxwell's early life were provided by Jemima Wedderburn's sketch-book, very fortunately saved from the recent fire at Glenlair and lent by Capt. Wedderburn Maxwell for the celebration. There one could see the child of three years of age gazing in awe at the fiddler at the servants' dance, wondering, no doubt, 'what was the go of it'; there, too, his escape from his unsympathetic tutor by paddling himself into the middle of a pond, together with other charming sketches of early life at Glenlair. The Institution of Electrical Engineers lent its portrait of Maxwell, and Dr. William Garnett sent the original of the well-known photograph of his later years.

As a final entertainment, the guests were shown the connexion of Maxwell's colour work with modern work on colour photography.

In 1861 Maxwell prepared for a Royal Institution lecture three lantern slides of a bow of ribbon taken through solutions of sulphocyanide of iron, chloride of copper, and ammoniated copper. The slides were projected on to a screen by means of three lanterns. Mr. Thorne Baker, of Messrs. Spicer, Ltd., reconstructed the projection, using the original slides, and then showed a colour film of the procession of delegates from Corpus Christi College to the Senate House which had been taken the previous day. The projection was very successful, the brilliant blue of Prof. Cabrera's robes being particularly well reproduced.

The proceedings closed by a banquet in Trinity College.

THE addresses presented on the occasion of the Clerk Maxwell centenary celebrations have been brought together and issued as a single volume.[*] The book forms a most fitting permanent memorial of Maxwell's achievements and personality, linking certain aspects of his work with that of Faraday, placing it against the background of his time, and showing its influence on those great movements in scientific thought which have completely revolutionised our outlook.

It is no easy matter either to review or to summarise adequately a volume dealing with a life which has touched and dominated so many activities of our modern world. Planck puts the matter in a nutshell when he points out that Maxwell's work has materially influenced two great regions of conceptual thought, the regions which deal with the physics of particles and with the physics of continuous media. In half a dozen masterly pages, Planck sketches the development of the kinetic theory, shows how Maxwell's great discovery of the velocity distribution law roused the interest and enthusiasm of Boltzmann, and how these two masters, marching along different ways, one attempting "to find the statistical laws of a complicated mechanical structure by considering the structure simultaneously in a number of different states, while Boltzmann, on the other hand, preferred to follow over a long period of time a single structure through its manifold changes of state", laid the foundations of the modern science of statistical mechanics.

There is no more fascinating chapter in the history of kinetic theory of gases than that which describes the difficulties encountered by the theory when dealing with certain irreversible processes. Here again these two pioneers followed very different routes, and Maxwell's artifice of looking on a collision as a rapid and continuous transition from the initial to the final state governed by a repulsive force which varied according to the inverse fifth power of the distance, roused Boltzmann to a high pitch of enthusiasm. His famous comparison of Maxwell's work to a musical drama is unique in the literature of science:

"At first are developed majestically the Variations of the Velocities, then from one side enter the Equations of State, from the other the Equations of Motion in a central field; ever higher sweeps the chaos of formulæ; suddenly are heard the four words 'put $n=5$'. The evil spirit V vanishes and the dominating figure in the bass is suddenly silent; that which had seemed insuperable being overcome as if by a magic stroke. . . . Result after result is given by the pliant formulæ till, as unexpected climax, comes the Heat Equilibrium of a heavy gas; the curtain then drops."

Sir J. J. Thomson's essay tells the story of Maxwell's greatest contribution to science—the theory of the electric field—with all the force and authority of one of whose influence on post-Maxwellian physics it can with literal truth be said, *pars magna fuit*. It is difficult in these days, when the concept of lines of force is a school commonplace, to realise the state of electrical science in 1855, when Maxwell's first paper appeared. An imposing mathematical superstructure had been built on the inverse square law and the notion of action at a distance, and, indeed, if we endeavour not to be wise after the event, we see that there is a measure of justification for Sir George Airy's dictum when he says that he "can hardly imagine anyone who knows the agreement between observation and calculation based on action at a distance to hesitate an instant between this simple and precise action on the one hand and anything so vague and varying as lines of force on the other."

---

[*] James Clerk Maxwell: a Commemoration Volume, 1831–1931. Essays by Sir J. J. Thomson, Max Planck, Albert Einstein, Sir Joseph Larmor, Sir James Jeans, William Garnett, Sir Ambrose Fleming, Sir Oliver Lodge, Sir R. T. Glazebrook, Sir Horace Lamb. Pp. vi+146+2 plates. (Cambridge: At the University Press, 1931.) 6s. net.

Nevertheless, although the exponents of the theory of action at a distance took little account of the properties of space, Faraday's fundamental experiments show that this neglect is erroneous. After all, it is necessary to take cognisance of such elementary results as those shown on rotating a coil (*a*) when a magnet is in the neighbourhood of the coil, (*b*) when the magnet is removed. Faraday expressed the difference by saying that space traversed by magnetic lines of force is in the electro-tonic state.

Maxwell's physics was that of the Scottish school, and he had a passion for exhibiting and explaining his views by means of a model. In his model of the magnetic field he represents "the lines of magnetic force . . . by cylinders rotating round these lines as axes, the magnitude of the force being represented by the velocity of rotation and its direction by that of the axis of rotation". The cylinders, in order that they may rotate in the same direction, must not be geared directly, but something of the nature of idle wheels must be introduced. The part of the idle wheels is played by electric particles, symbolised as small spheres. It is not difficult to see that changes in the magnetic field (that is, in the velocity of rotation of the cylinders) will produce motion of the spheres—that is, will give rise to an electric current; and it is the great virtue of the model that it suggests that changes in the electric force will give rise to motion of the cylinders—that is, will create a magnetic field. There is no need to labour the matter further. We may leave it here with Sir Joseph Thomson's comment that "the introduction and development of this idea was Maxwell's greatest contribution to Physics".

We have remarked on Maxwell's partiality for a model; and it is difficult, based as our mechanical views are (or were) on laws deduced from observation of large-scale phenomena, not to extrapolate our macroscopic conceptual world into the region of the infinitely small. So we obtain a concept of a gas based on billiard-ball mechanics; so we give the realities of elasticity and density to a luminiferous ether. Maxwell ran no such danger. His model was never confused with the physical reality (whatever that may be), and could be cheerfully discarded when it had done its work. "The changes of direction which light undergoes in passing from one medium to another are identical with the deviations of the path of a particle in moving through a narrow space in which intense forces act. This analogy was long believed to be the true explanation of the refraction of light; and we still find it useful in the solution of certain problems, in which we employ it without danger as an artificial method. The other analogy, between light and the vibrations of an elastic medium, extends much farther, but, though its importance and fruitfulness cannot be over-estimated, we must recollect that it is founded only on a resemblance *in form* between the laws of light and those of vibrations."

It is of this passage that Sir James Jeans remarks that it reads almost like an extract from a lecture on modern wave-mechanics.

In these two great divisions of physical science Maxwell's influence has been supreme. But any memorial of Maxwell which did not include some account of his wonderfully attractive personality would suffer seriously. Fortunately a few personal friends are still with us, and Dr. Garnett, Sir Ambrose Fleming, Sir Richard Glazebrook, and Sir Horace Lamb have added some precious details to that store from which many of us have been wont to glean—Campbell and Garnett's "Life".

Perhaps not enough has been made of Maxwell's remarkable genius as a writer of light verse. His mind was nimble, versatile, and scholarly; he had, moreover, that sympathetic understanding of an author which is the first essential for a successful parodist; and hence results the production of a volume of verse, small in itself, but of remarkably high quality. Much of his verse is technical, and its appeal is to a narrow audience; but such a parody of Tennyson as is seen in the well-known stanzas beginning

> "The lamplight falls on blackened walls"

is not unworthy of Calverley.

The autumn of 1931 has been a memorable period in the history of the physical sciences in Britain; it has seen the centenary of the British Association; it has seen the centenary of one of Faraday's fundamental discoveries; in celebrating the centenary of James Clerk Maxwell, we honour one whose life in its gentleness, its geniality, its single-hearted devotion to a lofty ideal is, equally with his contributions to science, a κτῆμα ἐς ἀεί—a treasure for all time.

ALLAN FERGUSON.

Henry Cavendish, 1731–1810.

OF all the many members of the Cavendish family who have made the name famous, none will probably be remembered longer than the distinguished eighteenth-century natural philosopher, the Honourable Henry Cavendish, the bicentenary of whose birth falls on Oct. 10. The founder of the fortunes of the family was the fourteenth-century judge, Sir John Cavendish, who was murdered in Jack Straw's rising in 1381, but from whose descendants came both the first dukes of Newcastle and the earls and dukes of Devonshire. William Cavendish, the fourth Earl of Devonshire, the statesman of the reigns of Charles, James, and William and Mary, became the first Duke of Devonshire, and it was from him Henry Cavendish traced his descent, being the son of Lord Charles Cavendish, son of the second duke.

Cavendish was born on Oct. 10, 1731, at Nice, where his mother, Lady Anne Grey, daughter of Henry, Duke of Kent, had gone for the sake of her health. He was educated at the school of Dr. Newcombe in Hackney, and in 1749, at the age of eighteen, entered Peterhouse, Cambridge. Four years later he left the University without, however, taking a degree. Little is known of his early manhood, but in 1760, three years after his father had been awarded the Copley Medal of the Royal Society for his "Very Curious and Useful Invention of making Thermometers", he, too, became a fellow of the Society, and six years later, after reading his first scientific paper, was also awarded the Copley Medal, "for his Experiments relating to Fixed Air".

Already deeply absorbed in scientific research, thence onward his study and laboratory claimed practically every moment of his life. His published papers were by no means numerous, but they firmly established his reputation, and as time went on he came to be regarded both at home and abroad as the foremost British natural philosopher of his age.

Cavendish occupied himself with many branches of physical science, including chemistry, meteorology, heat, magnetism, electricity, mathematics, and astronomy, but it was in the realm of chemistry that he first made his mark. He proved the elementary nature of hydrogen, he established the practical uniformity of atmospheric air, he was the first to show that water is not an elementary body but a compound of hydrogen and oxygen, and he discovered the composition of nitric acid. When sparking a mixture of common air and oxygen over potash he made observations which were not properly explained until Rayleigh and Ramsay in 1894 discovered argon. His great contemporaries included Black, Priestley, Scheele, Bergmann, Lavoisier, and others, whose work created a revolution in chemical science. A tremendous controversy for long raged around the question of who first discovered the composition of water, but it would probably never have occurred had Cavendish acted on Faraday's advice to investigators to "work, finish, publish".

The chemical researches of Cavendish were well known to his contemporaries; it has remained for the last two generations to learn of his many discoveries in electricity. Only two of his electrical papers were published in his lifetime, but he left behind him a mass of manuscripts and note-books which, though containing many 'pearls of scientific truth', were allowed to remain hidden for nearly a century. After the opening of the Cavendish Laboratory at Cambridge, the princely gift of the Chancellor, William Cavendish, seventh Duke of Devonshire, and the appointment of Clerk Maxwell as Cavendish professor of experimental physics, these manuscripts were placed in Maxwell's hands, and after much study were published in 1879. A further and enlarged edition of Cavendish's papers was issued in 1921, edited by Sir Joseph Larmor, Sir Edward Thorpe, and others. They showed that Cavendish had made electrical condensers and had measured their capacity, that he had anticipated Faraday's work on specific inductive capacity, and had completed an inquiry amounting to an anticipation of Ohm's law.

In another branch of science, geophysics, Cavendish is remembered for his capital experiment for determining the density of the earth. The plan adopted and apparatus used for the experiment were devised by the Rev. John Michell, rector of Thornhill, Yorkshire. He died before he could carry out the investigation, but his apparatus passed to the possession of Wollaston of Cambridge, and was given by him to Cavendish. The results obtained by Cavendish in 1784 were not far different from those obtained by later investigators working with more refined apparatus, and are a tribute to that care and exactness which characterised all his researches.

The character of Cavendish has baffled many inquirers. His habits were more those of a recluse than of a scion of a noble house. At first given an allowance of £500 a year by his father, after his fortieth year he was a man of immense wealth, and Biot after his death spoke of him as "le plus riche de tous les savants, et probablement aussi le plus savant de tous les riches". All his life he was shy, reserved, and taciturn, Brougham saying that "he probably uttered fewer words in the course of his life than any man who ever lived to four score years, not at all excepting the monks of La Trappe". Yet, from his bachelor home on Clapham Common, he would come to attend the weekly dinners of the Royal Society Club, and his library, housed in Dean Street, Soho, was available for all men of science. His life was written by Prof. George Wilson, who had to admit that Cavendish was singularly passionless: "An intellectual head thinking, a pair of wonderfully acute eyes observing, and a pair of skilful hands experimenting and recording, are all that I realise in reading his memorials". Of such a man anecdotes were sure to be told, and among them was the strange one of the manner of his death. Feeling his end was near, he said to his servant, "Mind what I say—I am going to die. When I am dead, but not till then, go to Lord George Cavendish and tell him—go!" He died on Feb. 24, 1810, at his house at Clapham, and on March 8 his remains were removed to Derby and interred in the family vault in All Saints' Church.

Obituary.

Sir Howard Grubb, F.R.S.

For more than sixty years, Sir Howard Grubb, who died at Kingstown, Co. Dublin, on Sept. 16, at the age of eighty-seven, was actively engaged in the design and manufacture of astronomical and other optical instruments. He was born in Dublin in 1844 and educated at a private school and at Trinity College, Dublin, as a civil engineer. His father, the late Thomas Grubb, F.R.S. (1800–1878), who was engineer to the Bank of Ireland, founded a small works near Charlemont Bridge early in the nineteenth century, where he manufactured for the

Bank some ingenious machines for engraving, printing, and numbering the bank notes. He took up practical optics as a hobby and quickly acquired great skill in the art of lens and mirror making. One of his first reflectors, equatorially mounted, was the Armagh 15-inch, in 1835. In 1865 he undertook, at the request of the president and council of the Royal Society, to design and manufacture a 4-foot reflecting telescope for Melbourne, Australia, which he completed in 1868. This instrument was the largest in the southern hemisphere until quite recently.

Thomas Grubb retired from business in 1868 and was succeeded by his son Howard, who had left Trinity College two or three years previously, in order to assist his father with the Melbourne telescope. In 1878 Howard Grubb contracted to build the 27-inch refractor and three domes for the Vienna Observatory. This telescope, at that time the largest existing refractor, was completed in 1881. Among other large instruments which he built were the 24-inch photographic refractors for Cape Town and the Radcliffe Observatory, Oxford, the 26-inch 'Thompson' refractor, and the objective of the 28-inch refractor for Greenwich, the 26½-inch refractor for the Union Observatory, Johannesburg, and the 40-inch reflector for Simeis, Crimea.

One of Sir Howard Grubb's most difficult undertakings was the construction, about 1890, of the 13-inch photographic refractors for the International Photographic Survey of the Heavens, of which he made seven. The conditions were exacting, the objectives requiring to be of the same focal length within very small limits, and the clock driving much more accurate than had hitherto sufficed for visual observations. In this connexion he perfected a means of controlling the driving mechanism by an independent pendulum, so that an error of a fraction of a second in the movement of the telescope was immediately detected and corrected. Numerous other improvements in telescope and revolving dome construction are due to him, and he is credited with being the first to suggest the rising floor, that at the Lick Observatory being partly of his design.

About 1905 Sir Howard Grubb invented and patented the submarine periscope, which was adopted by the British Navy. During the War he supplied about ninety-five per cent of these instruments required for the British submarines, and it was in connexion with these contracts that the Admiralty moved the works from Dublin to St. Albans. He returned to Dublin after the business was taken over by the late Sir Charles Parsons in 1925, but placed his knowledge and experience freely at the service of the new company which Sir Charles formed at Newcastle-on-Tyne, styled Sir Howard Grubb, Parsons and Co. The proprietors of these works are Messrs. C. A. Parsons and Co., Ltd.

Sir Howard Grubb was elected a fellow of the Royal Society in 1883 and knighted in 1887; he was also Hon. M.A.I. (Dublin), senior vice-president of the Royal Dublin Society, honorary member of the Royal Institute of Civil Engineers (Ireland), and was appointed, in 1913, scientific advisor to the Board of Irish Lights, in succession to the late Sir Robert Ball. He received the Cunningham gold medal of the Royal Irish Academy in 1881 and the Boyle medal of the Royal Dublin Society in 1912.

Sir Howard was in the first rank of men of science, and astronomy in particular owes him a great debt. His genial disposition made him a host of friends, and his death will be much regretted. He married in 1871 Mary Hester, daughter of George Hamilton Walker, M.D., of Louisiana, U.S.A., who predeceased her husband by a few months only. He leaves two sons and a daughter.

News and Views.

ON Oct. 14 occurs the centenary of the death of the French astronomer Jean Louis Pons, who in his day was famous as a discoverer of comets. Born at Des Peyres, Hautes Alpes, on Dec. 24, 1761, he entered Marseilles Observatory in 1789, in 1819 became director of a newly founded observatory at Marlia, near Lucca, and in 1825 director of the observatory of the museum at Florence, where he died. Between 1801 and 1827 he discovered no fewer than thirty-seven comets. One of these, discovered on Nov. 26, 1818, when Pons was at Marseilles, now called after Encke, was shown to have a period of only 3¼ years, and its return on May 24, 1822, as Encke predicted, was observed by Dunlop at the observatory of Sir Thomas Brisbane at Parramatta. This was the second instance, Halley's being the first, of the recognised return of a comet. The comet found by Pons on July 20, 1812, was also studied by Encke, who determined its period as 71 years. It was rediscovered by Brooks in America on Sept. 1, 1883.

THE subject of calendar reform is to be discussed in the present month in a League of Nations Conference at Geneva. In preparation for this meeting, the Parliamentary Committee on Calendar Reform has held a card referendum, addressed to a large number of representative people in Great Britain. A summary of the results is given in the *Times* for Oct. 1. It appears that 82 per cent of the voters are in favour of reform, provided that it can be obtained without too much dislocation. The 13-month scheme is evidently unpopular in Great Britain; there is a decisive majority against it. Ninety per cent of the voters favour a stabilised Easter; this, however, apart from public holidays, is an ecclesiastical, not a civil matter, and it will not lie within the scope of the Geneva Conference. The *Times* summary does not give any information on the question of putting certain days outside the normal reckoning of weekdays. This is one of the points that encounters a good deal of opposition, both from religious motives and from reluctance to discontinue a time-unit that has been running without a break for about three thousand years.

ACTING on the discovery of the skeleton of a Bushman on the farm of Mr. Fred. S. Wells in the Zuurberg Mountains, Mr. F. W. FitzSimons, the Director of the Port Elizabeth Museum, excavated the site and obtained four more skeletons. One was buried in a sitting posture, the rest flexed and on their sides. With each skeleton there were bracelets of stone and ivory, necklaces of finely worked ostrich egg-shell beads, pygmy stone implements, and a miscellaneous assortment of the typical larger kinds. The Zuurberg mountains are some fifty-five miles from Port Elizabeth, and the site of the find is on top of a mountain, a mile on the Port Elizabeth side of the Zuurberg Hotel. From the nature of the soil overlying the skeletons and other evidences, Mr. FitzSimons believes the burials were made about a thousand years ago. In 1922, it will be recalled, Mr. FitzSimons, assisted by Mr. Fred Wells, unearthed nine skeletons. This, then, is the second discovery in the Zuurberg of fossil Bushmen of pure lineage totally untainted by any fusion with other races.

A NEW world air speed record of 408·8 miles (657·76 kilometres) per hour was created by Flight-Lieut. G. H. Stainforth at Calshot on Sept. 29. The seaplane used was one of the Vickers-Supermarine *S 6 B*, specially built for the recent Schneider Trophy competition, fitted with a Rolls-Royce *R* engine and a special airscrew to suit the somewhat different conditions that arise in the relatively short bursts of maximum speed. During part of the run a speed of 415·2 miles per hour was recorded. It is estimated that this engine was giving 300 horse-power more than the one used during the Schneider trials, which was rated at 2300 horse-power. A special fuel mixture of petrol, wood alcohol, and tetra-ethyl was used. The wood alcohol was tried for the first time in order to reduce the engine temperature at full power, as the problem of dissipating the heat generated without introducing extra radiating surface with its accompanying head resistance has proved to be the most serious one on these machines. The tetra-ethyl was obviously used for suppressing pre-ignition and engine knock.

THE actual observed straights were flown at a height of 50 metres according to regulation, and Stainforth made the turns by climbing into them and diving out again on to the straight. This manœuvre has the advantage of reducing the speed on the turn and regaining it from the momentum of the dive. Carried out at speeds in the neighbourhood of 400 miles per hour, it is a very real evidence of the extraordinary skill and cool-headedness of the pilot. It was noticeable that after the first run, when once the engine was thoroughly warmed up and the pilot had obtained the ideal throttle setting, there was no further sign of any trail of smoke from the exhaust. The balance between the engine requirements and the amount of fuel forced into it by the supercharger was being maintained so delicately that the engine was just consuming all the fuel supplied to it, thus paying tribute to the accuracy of the work of the engine designer, the blender of the fuel, the mechanics responsible for the final tuning up, and the pilot who was handling it in flight.

A MEETING of the Lord Mayor and Sheriffs' Committee has been held in the Guildhall, London, to take steps in connexion with the festivities on Lord Mayor's Day, Nov. 9, and it is stated (*Times*, Oct. 1) that the Lord Mayor elect, Alderman Maurice Jenks, desires that the Show should contain a pageant designed to illustrate the assistance scientific discoveries have given to industry during the past half-century; and the effect invention and the practical application of invention have had upon the daily life of the people, and especially the Londoner. While the difficulties of turning such an idea into a spectacle suitable for the London streets are obvious, it is hoped that they are capable of being overcome. With regard to this, we think that if the great power companies, the shipping companies, the cold-storage companies, the technical colleges, and similar bodies are asked to co-operate, there should be no difficulty in arranging a very striking display. The adoption of electric light and power, the practice of refrigeration, the use of the internal combustion engine for motor cars and aeroplanes, communication by wireless telegraphy and telephony, are but a few of the gifts of scientific discovery and invention to practical affairs in recent times, and there is probably no side of life in London which has not benefited by modern invention. We wish the promoters of the scheme every success.

AT the annual meeting of the Australian National Research Council, a report by a sub-committee appointed in 1930 to consider a change in constitution was received and adopted. The recommendations were: that the name of the Council be changed to that of Australian Academy of Sciences; that the Academy be incorporated under the Companies Act of New South Wales and registered under the Companies Acts of other States; that the number of members be increased from 100 to 150; that the publication of a journal be undertaken; and that one of the objects of the Australian Academy be to act as the National Research Council. The adoption of the report was unsuccessfully opposed by representatives of a society recently constituted in Canberra under the title of Royal Society of Australia. The action taken in Canberra, without general consultation with leaders in scientific work elsewhere in Australia, was adversely criticised, the majority taking the view that the reconstituted Research Council was the appropriate body to fulfil the functions of a Royal Society for the Commonwealth.

LORD BLANESBURGH, Prime Warden of the Worshipful Company of Goldsmiths, delivered the inaugural address at the formal opening on Oct. 5 of the thirtieth session of the Sir John Cass Technical Institute, London, on Tuesday last. Lord Blanesburgh said that he hopes that the proposals which have been made and are so near fruition for the extension of the Institute will not be indefinitely postponed, and that there will always be secured by the maintenance of its activities a supply of those skilled in applied science to meet the demands made by the future. Swift and unsettling world changes have taken place during the past thirty years. Aviation and wireless are two discoveries of science which alone have revolutionised, and will revolutionise, the world as it was known thirty years ago. Such discoveries, however, have not prevented political unrest nor economic depression, each of which is probably attributable to the fact that, as result of new discoveries, old-established customs pass away and old-established industries are made obsolete. The world to-day needs young minds, ready to face the new situation with fearlessness and courage, and without hesitation if the time comes to destroy the ideals of the market that have had their day. Fortunately, educational help is available for the best young men and women of the land, so that that which has been obtained for humanity by the genius of inventors and discoverers may not be lost by the apathy or ignorance of their successors.

IF the machinery of science, Lord Blanesburgh continued, were withdrawn or went out of gear, and the elaborate structure on which the supplies of comforts, luxuries, and conveniences depend were to fail, mankind would be left defenceless and unable to provide even the barest necessities of life. It is accordingly essential that there should always be those ready to repair the machine when it falls into disrepair, and there must indeed be a new supply of those well qualified to keep the machinery going by themselves being abreast of all new discoveries. Civilisation is on its trial; it could not survive another war. It may even perish without one. The battle for its defence may be fierce and prolonged, but, if human nature remains what it has always been, in the long run it will be to the efficient, to him or her of strong mind and high character. To the young people who have enlisted in this crusade and who have enrolled themselves in a high service to their fellows, Lord Blanesburgh said he would have them be strong and of a good courage, and he would also have them, if need be, to live dangerously. No ideal should be too high, and there should be a healthy contempt for the second-rate.

IN his report as the Entomologist to the U.S. Department of Agriculture, for the year ended June 30, 1928, Dr. C. L. Marlatt summarises the manifold activities of his charge. Owing to the changes authorised in 1927, which led to the establishment of a new organisation designated the plant quarantine and control administration, the work carried out by the Bureau of Entomology in co-operation with the Federal Horticultural Board, in enforcing quarantine measures relating to many of the most important introduced pests, has been transferred to this new body. It had, for a long time, been felt that the growing amount of regulatory work of this kind was handicapping research on the biology and control of insect pests which form the primary function of the Bureau. During the year under review, Dr. L. O. Howard retired from the post of chief of the Bureau, which he had held since 1894. It is, however, gratifying to note that Dr. Howard will remain in the Bureau, under the title of Principal Entomologist, to follow up lines of work bearing upon his special interests. The report, like its predecessors, deals with an immense range of investigations bearing upon agricultural crops and animals, insect-borne human diseases, forest pests, apiculture, and certain domestic troubles, such as furniture pests and the ravages of clothes moths. In addition to work of this character, progress with a general insect-pest survey, and taxonomic investigations carried out in the U.S. National Museum, also come under review.

A FEATURE of particular interest in Dr. Marlatt's report concerns the prevalence of insect life in the upper air. By the adoption of special insect-collecting traps, carried between the wings of aeroplanes, it was found that an unexpectedly large number of insects are present in the upper air. Many of these are species which possess little or no power of flight and are consequently carried involuntarily by air currents. It would seem from the records so far obtained that the stronger flying species are capable of largely controlling their flight so as to be able to confine themselves to relatively low altitudes. On the other hand, species which have never been suspected as being wind-borne have been apparently carried by upward air currents and so caught at great elevations. There is every indication that the problem is one of definite practical importance, particularly in relation to quarantine measures which are solely concerned with restriction of spread on land.

WE are so used to regarding Michael Faraday as a physicist that it comes as a surprise to read an article by Prof. Fraser Harris, in *Discovery* for October, in which he discusses a lecture given by Faraday at the age of twenty-seven to the London City Philosophical Society in 1818. The title of the lecture was "Observations on the Inertia of the Mind". In this lecture he pointed out that apathy represents the inertia of a passive mind, industry that of an active mind. In 1899, Prof. Fraser Harris, unaware of the lecture by Faraday, put forward his hypothesis of 'functional inertia', the functional inertia of rest and the functional inertia of movement. The former is expressed by the latent period, the latter by the phenomena of after-discharge. This principle, Prof. Fraser Harris points out, has been confirmed by Spearman when he says, "Cognitive processes always both begin and cease more gradually than their apparent causes". Even so far back as 1679, Hobbes had said, "Like water troubled, an organ of sense will remain in motion after the removal of the exciting agent". The most recent work in neurology confirms the existence of inertia. Spearman directs attention to the gradual rise and fall of sensory intensity and the latency and after-discharge of reflexes. Blake-Pritchard introduces "inertia of the system" and

Reviews.

Paul Tannery and the History of Science.

Mémoires scientifiques de Paul Tannery. Publiés par L.-L. Heiberg et H.-G. Zeuthen. Tome 10 (Supplément au Tome 6) : *Sciences modernes, généralités historiques, 1892–1930.* Édité avec la collaboration de Joseph Pérès. Pp. xvi + 500. (Toulouse : Édouard Privat ; Paris : Gauthier-Villars et Cie, 1930.)

THE last volume of Tannery's "Mémoires" has a special and immediate interest in view of the recent International Congress of the History of Science and Technology. We have in it the latest views and full evidence of the quality of a man belonging to a class too little known and much needed in England. He was a scholar of the most profound and unquestioned thoroughness, who gave his life to research in a branch of learning which we regard as a side issue but is in fact at the centre of human progress, namely, exactly how men have come to think as they do about scientific questions, especially in the realms of mathematics, physics, and astronomy. On the first of these matters he was at his death probably the most completely informed man in the world. But his special quality, which should commend this volume to English readers, was his constant effort to see the details, which he knew so well, as part of the general process of thought. He was in fact a philosopher as well as a specialist in scientific history. To English students, as a rule, it seems sufficient to know what the particular group of men in the past were working at, and the very idea that there is a general movement of thought is suspect. For this fault the work and temper of Tannery and men like him are a wholesome corrective. They are to be found more abundantly in all other countries than our own. France and Germany lead the way, with Italy as a good third, while America, more open-minded than ourselves, welcomes the spirit and is vigorously following in a more popular way.

It was a tragedy in the life of Tannery that on the occasion when he might have found a large sphere for his views and activity in Paris, personal and sectional interests were allowed to exclude him. A chair had been founded in the Collège de France in the spirit of Comte, for teaching the general history of science, and it was occupied on the first occasion by Pierre Laffitte, who was both Comte's titular successor and also well qualified by his own attainments and influence to fill it. On the death of Laffitte, it was generally expected that Paul Tannery would be chosen, and his name was actually sent up to the Minister by the professors on the committee for appointment. At the last moment, however, pressure was brought to bear by the more orthodox followers of Comte, and a specialist on physics was appointed instead. It was a grievous blow to Tannery and a serious loss to the establishment of a philosophic view of the history of science both in France and throughout the world.

Such men are rare anywhere, and in England we have scarcely yet begun to reckon with their possibility or the desirability of encouraging them. No university in Great Britain has such a chair, though they are to be found in Germany and are frequent in the United States. Nor is there any section of the British Association devoted to the history of science.

The volume before us opens with a pathetic note by Mme. Tannery lamenting the loss of Heiberg, who with Zeuthen had been helping her in the production of her husband's "Mémoires". Others in France have come forward to make possible the completion of the work, and its interest makes one hope that more may be done, especially on the lines of completing the short general history of science up to 1850 which he had sketched and of which several lectures printed here would form part.

Tannery had a strong view that for such a general history no attempt should be made to bring the narrative up to date. We should choose a point at which the sciences have taken a definite and ascertainable shape, and the object of our study would be to show how they had reached it. If we attempt to come later down, the conflict of hypotheses and the complexity of the new matter are so great that no definite impression can be obtained. Time must elapse before the seething mass settles down into a shape that can be visualised. These are all considerations connected with his governing idea of synthesis. We need some distance of vision before science as a whole makes a connected show of its natural articulations, and when that has been gained, we may attempt to go further and see the relations of the scientific side with the other aspects of civilisation. Tannery foresaw that larger synthesis, but had little hope of being able to contribute to it himself.

Everyone, however, who has even the smallest interest or knowledge, would find these scattered papers inspiring. The syllabus he drew up for a course in the history of science for the highest class of a *lycée* is the best that we have seen. It is sane, clear, and well-balanced. He begins himself from the conservative, classical point of view, giving by far the largest place to the Greeks. But he was always ready to modify his preconceptions in view of fuller knowledge or with maturer judgment. His treatment of Comte is an admirable example of this. Starting with the deepest sympathy and appreciation of Comte's work from the philosophical and social point of view, he goes on to re-think and correct the details. In this way the law of the three stages is examined and the truth in it separated from the error. As a correction of the historical evolution of sciences from the most abstract (mathematics) to the most concrete (biology and sociology), he shows the high importance and seniority of medicine.

The book is full of interesting matter of this kind, all based on exhaustive knowledge and expressed with the calm and clarity of a master.

F. S. MARVIN.

Ethnological Survey of a South African Tribe.

The Bavenda. By Dr. Hugh A. Stayt. (Published for the International Institute of African Languages and Cultures.) Pp. xviii + 392 + 48 plates. (London: Oxford University Press, 1931.) 30*s.* net.

IN her able introduction to this work, Mrs. Hoernle points out with regret that no adequate monograph on any of the South African tribes has been written during all the years in which black and white have been in contact in that subcontinent. This regret will be shared by many, and it may, moreover, be considered as remarkable evidence of a failure to realise that the natives of South Africa have been and still are the greatest asset which the country possesses; for it is mainly by the help of their brawn that the present stage of prosperity has been achieved, and thus careful study of their life history is essential. It is true that Callaway wrote of the Zulus, Lagden of the Basutos, and Stow of the native races; but for all that, Mrs. Hoernle's contention is correct. The only two works dealing with the natives of the southern half of the continent which are comparable with Dr. Stayt's monograph are Smith and Dale's "Ba-Ila" and Junod's "Life of a South African Tribe", but the subjects of both of these works live outside the Union of South Africa. Dr. Stayt's work comes as a revelation, for, as an occasional visitor to South Africa, one felt that owing to long-continued disintegration of the tribes it would probably be impossible to gather up the threads and construct a real picture of the indigenous culture of any native tribe in that area. The author has, however, been fortunate enough to discover that the Ba-Venda, living as they do in the valleys of the Zoutpansberg Range of the North Transvaal, have tenaciously preserved their ancient traditions and culture up to present times.

The achievement is all the more remarkable inasmuch as the author suffers from one of the gravest disabilities an anthropologist can experience—blindness. In view of this, it is amazing how he can have accomplished so much; his courage and perseverance command the deepest respect, and the devoted assistance of his wife must not be ignored. It is, moreover, especially fitting that Dr. Stayt should be a South African, and we trust that this admirable piece of research may stimulate many other workers in the Union to emulate his example. Dr. Stayt's monograph covers the field in a very systematic manner, commencing with a description of the terrain, then dealing with the history, unfortunately, however, the author has to confess that the latter is rather vague and fragmentary, and evidence as to the early migrations of this stock will have to be pieced together bit by bit from investigations, yet to be made, farther to the north. He then deals in detail with their daily life, food, and industries, and so on; proceeds to describe the life of an individual from birth to death, their social relationships, form of government, religion, magical beliefs; and so to their folklore—in all, a very complete conspectus.

As is the case in many African tribes, the Ba-Venda are a composite people which have now become a compact entity, and it could not have been easy to disentangle the elements of their culture which were derived from the various components. The problem becomes particularly acute where an effort is made to ascertain which of their physical characteristics belong to the original Venda stock and which are superimposed by comparatively recent intermixture with the Sutho people and others.

The Ba-Venda provide a typical example of Bantu culture. The word 'Bantu', of course, refers only to a language group, but in most cases those who use a Bantu tongue exhibit other affinities which betoken connexion with the same racial stock. Anyone, for example, who is acquainted with the social anthropology of so-called Bantu tribes so far north as Kenya cannot fail to be impressed by the recurrence of social customs, religious beliefs, etc., in spite of the distance intervening; space will not admit of great detail, but these recurrences are so numerous as to preclude the possibility of separate but similar development. The sacred stones erected in the villages as a representation of their ancestors have their parallel in places as remote from each other as North Kavirondo and Kikuyu; the re-burial of the remains of a chief at the ancestral home of the tribe Phaphuli is also a feature of the Awa-Wanga of North Kavirondo; the placing of a stone in a tree, by a traveller, to delay the setting of the sun until his journey is concluded—not Bantu this time, but a custom in vogue among some of the Hamitic tribes of Kenya. These are a few examples taken at random. To find the birthplace of other customs we should probably have to make a comparison with tribes to the north-west of their present habitat.

There is little doubt that when the ethnological survey of Africa is more advanced we shall, by careful analysis of customs and beliefs, be able to trace with considerable accuracy the past migrations of native races and discover the various racial elements which go to make up the assemblages now designated as tribes.

The chapter on "Puberty and Initiation" is an important one, for, owing to the secrecy of the ceremonies attending the latter, it is but rarely that the European investigator is able to make a detailed study. As is usual, there are many features repugnant to European sentiment, but for all that, the importance of these ceremonies as a part of native life should not be under-estimated. The discipline and even suffering undergone by the initiates is a crude form of educational training, and the lesson of obedience to the tribal law learnt at this period is one which leaves its mark for life. It is a potent cement which helps to hold a tribe together. While sympathising to some extent with good-hearted missionaries who strive to induce governments to crush these practices, we would venture to suggest that legislation against a custom is rarely effective; it only tends to drive it underground and to produce a lasting sense of injustice. Rise in culture will in time cause these customs to die, but what will replace them? It is the duty of those responsible to see that the substitute is ethically effective.

The religion of the Ba-Venda conforms to the pattern evolved by the stock. There is the mysterious monotheistic deity called Ralu vhimba, but, as is usual, he has but little appeal to the ordinary man, who is more concerned with placating and giving due service to the spirits of his ancestors. Earth tremors are particularly identified as manifestations of the Supreme Deity.

In connexion with medicine and magic, a careful description is given of certain curious divination bowls used by this tribe. These are of considerable importance, for it is believed that we here have evidence of the native origin of the so-called zodiacal bowls found at Zimbabwe and upon which the school which pleaded for Phœnician origin laid so much stress.

It is only desired to lodge two minor criticisms of this exhaustive monograph: the print is rather small, and the price of the book is high.

(5) *Man and the Stars.* By Harlan True Stetson. Pp. xiii + 221 + 31 plates. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1930.) 12*s*. 6*d*. net.

(1) HERE is astronomy to suit all tastes. We may go even further, for Sir James Jeans's book has the power to create a taste which in large part it satisfies. It embodies all the rare qualities

of exposition for which the author is justly famous, and the treatment, even of subjects with which Sir James's pioneer work is not intimately concerned, bears the stamp of originality. The book is avowedly and actually one to be read for pleasure rather than for profit (although, needless to say, profit inevitably follows from the reading), and we may truthfully add, in the language usually employed in describing literature of this class, that there is not a dull page from start to finish. About fifty of the pages are occupied by excellent reproductions of the finest of astronomical photographs, and, indeed, the book as a whole appeals more to the senses than to the mind. It originated in a series of wireless messages to the ear, and it carries the reader in a magic rocket through space and time, inviting him the while to use his eyes. Maps of the sky, with descriptions of the constellations and tables of simple data, are added as souvenirs of the journey.

Regarded in this light the book is almost beyond criticism, but we cannot quite shake off an awkward suspicion that theoretical astronomy is scarcely a legitimate subject for a novel. Seeing is believing, and because of its vividness the pageant which passes before our eyes leaves us unaware that it is largely an imaginary representation of what the astronomer merely feels in his blind groping among the mysteries. Alternative representations are of necessity excluded, and where a warning that we may be deceived is unavoidable, it is given almost reluctantly, with the result that—to change the metaphor—we are given a sumptuous meal when what we need is an appetite. The uninitiated reader is likely to lay the book down with the feeling that the most important secrets of astronomy have been read; he is not likely to feel with Galileo the overwhelming force of "those wise, ingenuous, and modest words—*I do not know*". But, all the same, he will have had a delightful experience.

(2) Prof. Rosseland's book is of an entirely different character. Those who are familiar with the excellent "Struktur der Materie" series to which it belongs will have a general idea of its scope, and will need no assurance of the excellence of its printing and production. The book, the author tells us, is intended as an introduction to astrophysics for physicists who are concerned with astronomy and astronomers who are concerned with physics, and although limits of space necessitate a high degree of condensation and the omission of certain parts of the subject—particularly those concerned with solar magnetism—a great deal of ground is covered in a very satisfactory way.

Prof. Rosseland writes with commendable clearness and strikes just the right balance between impartial exposition and critical selection. Considering the rigidity of the treatment, mathematical formulæ occupy a remarkably small proportion of space, and are not difficult. The book is, however, essentially theoretical, the data of observation being mainly confined to the first dozen pages. The chief subject of the book is the physics of the interiors and atmospheres of stars, and the treatment of this, in fact, together with a chapter of thirty-five pages on the nebulæ, comprises almost the whole volume. It is a pity that Milne's new approach to the problem of stellar structure was not in time to be included, for it might have shifted somewhat the general point of view which the author adopts in facing this problem. Prof. Rosseland's view of the present situation would be of considerable interest. There are several illustrations, which are well reproduced.

(3) More food for the specialist is provided by Miss Payne, but her book, unlike that of Prof. Rosseland, is almost entirely devoted to observational material. It is in no sense a practical handbook, for methods of observation are never described, although the difficulties inherent in them are sometimes mentioned in so far as they bear on the validity of possible interpretations. Neither is it a mere collection of data; the facts are throughout regarded in the light of existing theory, with which the reader is presumed to be familiar.

The book meets an urgent need, and meets it very adequately; the provision of 110 tables in addition to complete catalogues of the *c*-stars and Cepheid variables reveals its character better than any verbal description could do. From one point of view the book may be regarded as the author's "Stellar Atmospheres" of 1925 brought up to date, but the metamorphosis is almost complete, for the study of spectrum line contours, then barely begun, forms the backbone of the present volume. By a star of 'high luminosity' is meant a star brighter than visual absolute magnitude -2. Such stars, although they form an almost negligible fraction of the stellar universe so far as numbers go, are extremely important—first, because they provide almost our only means of estimating the distances of remote stellar groups, and secondly, because they include at least the vast majority of variable stars and have a special significance in the theory of stellar constitution. The book is saturated with Miss Payne's own contributions to the subject, and astronomers will be grateful to her for making them available in so compact a volume.

(4) Dr. Shapley's "Flights from Chaos" is mainly a descriptive classification of material systems from the most elementary corpuscles to the "Cosmoplasma" and beyond. In this aspect it will be of interest to astronomers generally. The classification is systematic and comprehensive, and much of it will probably command general assent, although in some respects it would seem that the artistic passion for a general classification has triumphed over the scientific necessity for a fundamental one. It is doubtful, for example, if the æsthetic satisfaction of grouping diffuse nebulæ with comets and planetary nebulæ with solar systems is a sufficient compensation for separating two types of nebulæ which appear to differ only in accidental circumstances. Dr. Shapley's predilection, however, is revealed on p. 132, where he remarks of a certain classification that it "has the advantage of providing many categories without suggesting any hypothesis, evolutionary or otherwise". We know that a classification may deceive, but is the best remedy to strike it dumb ?

The appeal of the book, as exemplified by the opening, is directed towards the general public, and readers of that class who scan the first chapter will certainly be tempted to proceed. The author's enthusiasm for his subject, however, soon takes charge of his pen, and by the time the reader has reached, say, the chapter on "Double and Multiple Stars", he finds himself expected to know by instinct the meaning of such terms as 'spectroscopic binary' and 'optical double'.

Dr. Shapley is never dull, however, and the book would be very pleasant to read were it not for the appearance on almost every page of a minute, undescribed sketch of some astronomical phenomenon or diagram which, as often as not, bears no relation to the subject there discussed, and is frequently woven into the initial letter of a word. Possibly this way of presenting things is familiar to trans-Atlantic readers, but to us it suggests that the flight from chaos has been less successful than might otherwise have been imagined.

(5) Prof. Stetson's book is like a very nice picture badly bespattered with mud. It is as elementary as Sir James Jeans's book, but it has a wider purpose inasmuch as it aims at tracing the influence of astronomical discoveries on man's reactions to his environment. On the whole, it satisfies very well the fundamental requirements of such a purpose. It creates the right atmosphere, and, occasionally, one experiences the shock of pleasant surprise, so rarely received from scientific books, which accompanies the reading of just the right word or phrase. More often, however, the surprise is unpleasant. The book abounds in blemishes of almost every kind—faults of expression such as the excessive colloquialism of "hiding in jest a prayer to God, he (Galileo) shoved off together those two iron masses", or the errant metaphor in "I have sought to convey some viewpoints which I have often embodied . . ."; errors of scientific fact, such as the account of the spectrum of the strontium flame, which suggests that the author has not seen what he attempts to describe; errors of history, such as the ascription of the scurrilous "Ye men of Galilee" sermon to Scheiner instead of to Caccini, of the pioneer work in radial velocities to Vogel instead of to Huggins, and of the discovery of the cosmic rays, and even the electron, to Dr. R. A. Millikan of California. The printing shows the same qualities as the writing, for while it is clear and pleasant to read, it contains far too many mistakes. If another edition is called for, we hope the book will be thoroughly revised; it is so good that it is a thousand pities it is not better. H. D.

Strength of Materials.

Materials and Structures: a Text-book for Engineering Students. By Dr. E. H. Salmon. Vol. 1: *The Elasticity and Strength of Materials.* Pp. x + 638. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1931.) 15*s.* net.

Strength of Materials. By Prof. S. Timoshenko. Part 1: *Elementary Theory and Problems.* Pp. xii + 368. 15*s.* net. Part 2: *Advanced Theory and Problems.* Pp. xi + 401-735. 18*s.* net. (London: Macmillan and Co., Ltd., 1931.)

NO section of engineering science has been so frequently dealt with in treatise or textbook as that which provides the title common to both publications before us. Within the past decade there have been several notable efforts along similar lines and with equally ambitious aims. Yet the older textbooks on the subject did not fail to reach high standards. There must clearly be special reasons for these newer and repeated attempts. These reasons are not far to seek. Methods of analysis have been enriched by fresh contributions; applications to practical matters have been widely extended; advances of great value have been made in experimental technique; and new lines of research have been rapidly developed. On every score the somewhat stereotyped forms and standardised treatment of the older books have been superseded.

Modern engineering makes a demand upon knowledge of the properties of materials which shows up the methods of design of a generation ago as processes requiring, relatively, neither great skill nor nerve. A few simple values, a little theory, and a large factor of safety dealt effectively with most cases. The advent of the high speed rotor, the internal combustion engine, the high pressure, high temperature boiler, and the countless problems which have advanced in their train, have altered all this. The few simple values have been subject to forced growth by the development of more subtle methods of testing; the somewhat casual use of simple theory has had to give way to more exact methods of calculation; and the factor of safety has shrunk in size and lost flexibility. The continued development, experimental use, and establishment of a host of new materials, and the treatment and testing thereof, complicate all issues and confuse the factors of applicable knowledge. Any author facing an adequate treatment of such a subject in such a condition is confronted with serious problems of matter and classification. The former is formidable in quantity; the latter difficult to order. A comprehensive knowledge is an essential; but a clear idea of values and courage in selection are equally so, if range, balance, and conciseness are to be achieved. The adequate and yet not too cumbrous textbook is probably more difficult to produce than the treatise; which perhaps explains an observable tendency in publications of the kind.

Dr. Salmon's book is the first volume of a treatment of materials and structures, to be completed with a second volume mainly on the latter subject. The present volume deals wholly with what is understood technically by strength of materials, and the treatment occupies more than 600 pages of well-packed text. Prof. Timoshenko takes fully 700 pages, in two volumes, to deal with the subject. The relative loading per page is such that probably Dr. Salmon's book contains the greater total length of text. In addition to extensive analytical developments, both authors give sections on the experimental and empirical aspects of the subject; but whereas in Dr. Salmon's volume more than a third of the space is devoted to this, Prof. Timoshenko has not much more than a tenth set apart for the purpose. These relative spaces provide a clue to the main points of contrast. The first author is presenting a comprehensive textbook, showing both sides of the subject with reasonably equal thoroughness; the second provides an example of the analytical expert who adds a chapter on experimental aspects for completeness. It must be added, however, that Prof. Timoshenko enriches a great many of his analytical discussions with clear and valuable summaries of the appropriate experimental facts and conclusions.

The chapter divisions of Dr. Salmon's analytical section and of Prof. Timoshenko's first volume (elementary theory and problems) are very similar in headings and reflect the usual order of development through simple stress, complex stress, bending theory, combined bending and direct stress, combined bending and twisting, etc., and strain energy. Within each chapter the first author deals with both the elementary and advanced problems appropriate thereto, so far as his intentions go; whereas the second author postpones the most difficult lines of development to the second volume. Prof. Timoshenko's advanced volume contains, in addition, some special chapters, such as that on buckling of bars, plates, and shells, and that on stress concentration. Dr. Salmon gives a chapter on vibrations and actual speeds, and two others dealing with formal mathematical theory and its applications. He treats the standard lines of work with great clearness, and develops all essential matter with that degree of detail which is desirable if a book is to be of real value to students. His development of bending theory is useful and concise, although full value is scarcely extracted from the Mohr method of treating deflections; and it is something of a fault not to present the Macaulay method. There is a useful resurrection of the Claxton-Fidler procedure of characteristic points. Prof Timoshenko handles general processes with great power and brevity, the latter quality, to some extent, telling against ease of reading from the student's point of view; but there is that individuality in the methods and wide range in the problems that marked the previous publication on applied elasticity (by Timoshenko and Lessels) and still more notably characterises these new volumes.

It might be contended that the subject of strain energy should be treated earlier than either author has arranged. The idea should be made to thread the whole subject, and the Castigliano theorem—which Dr. Salmon presents, but does not so designate—could be put to greater service in the earlier parts. It is also open to question whether vibrations and critical speeds should now be looked upon as a theme for one chapter of a book on materials. The subject has grown in extent and importance to such a degree that it deserves special treatment. Prof. Timoshenko has a separate book on this topic.

In treating the experimental side of the subject of materials, one of two principles of attack may be adopted. A general report of testing methods and mechanical properties may be compiled, or a general essay on the significance in design of modern materials testing and properties may be attempted. On the whole, the former is Dr. Salmon's method and the latter represents the attitude taken up by Prof. Timoshenko in his shorter discussion. Both treatments are very readable and give due and accurate weight to such lines as fatigue and high temperature effects. Dr. Salmon has a final chapter introductory to the study of metallography, which should be of distinct service and does for the experimental side what his equally interesting chapter on general mathematical method does for the analytical, namely, stimulates interest in the more profound processes of study.

These volumes are all copious in references to original papers and other sources of information. Dr. Salmon has adopted an exceedingly valuable plan of arranging a full and classified bibliography at the end of each chapter, which compares very favourably with the more usual footnote method followed in Prof. Timoshenko's volumes. But adequate reference is a strong feature of both works and, in conjunction with the wide range and the excellence of treatment, should render them of distinct service to advanced students and technical engineers.

Extinct Volcanoes of Western Scotland.

Memoirs of the Geological Survey, Scotland. The Geology of Ardnamurchan, North-west Mull and Coll. By J. E. Richey and Dr. H. H. Thomas; with Contributions by E. B. Bailey, J. B. Simpson, V. A. Eyles and the late Dr. G. W. Lee; with Chemical Analyses by E. G. Radley and B. E. Dixon. Pp. viii + 393 + 7 plates. 10*s*. net. Sheet 51: *Coll.* Scale of one Inch to a statute Mile. Third edition. Colour printed. 30½ in. × 22½ in. 3*s*. net. (Edinburgh and London: H.M. Stationery Office, 1930.)

ARDNAMURCHAN, the most western point on the mainland of Scotland, is a peninsula of gneiss cape- [illegible] the remains of extinct volcanoes. It project [illegible] he gap between Mull and Skye and is exposed [illegible] e full force of Atlantic gales. Its battered clift [illegible] nd the landmark formed by its ancient volcanoes are familiar to all who pass by sea along the Western Isles. The geology of the peninsula is now for the first time adequately described in a well-illustrated and excellently compiled memoir of the Scottish Geological Survey, and is accompanied by sheet 51 of its one-inch maps. The sheet, in addition to western Ardnamurchan, includes the island of Coll and north-western Mull. Each of these areas has a very different geological history. Coll is one of the islands composed of Lewisian gneiss. North-western Mull consists of basalt lava-flows from the vents in the central part of the island; and western Ardnamurchan has as its chief feature the dissected base of a huge volcano.

One interesting feature of Coll is the occurrence of numerous glassy rocks due to fusion by crushing, for which, as is remarked in the present memoir (p. 25), "the term flinty crush-rock has come into general use among Scottish geologists". The adoption of this term in Scotland in regrettable. Flint is formed of organic silica, deposited from solution. These glassy rocks are of far more complex composition than flint and have solidified from a molten state. Prof. Shand's name of pseudotachylyte is more appropriate. The description of these rocks as flinty, instead of as glassy, is one of those illogical usages which have done so much to prejudice geology as a subject in general education. The vitrification of these rocks in Coll is shown to be pre-Torridonian; it is not, as may be possible elsewhere in Scotland, due to movements of the age of the Moine thrusts.

The main interest in this volume is its important contribution to the Kainozoic volcanic history of Scotland, with its repeated testimony to the truth of Judd's conclusion that the igneous masses of the Western Isles and of Ardnamurchan are the remains of a series of great central volcanoes like those of Hawaii and Etna. This view was for long, as the authors remark, generally rejected in favour of Sir Archibald Geikie's theory that the volcanic rocks were discharged by fissure eruptions and not from isolated vents. The fissure eruption theory was shown to be inapplicable in the main to Mull in a former Survey memoir, which held that it might still play a minor rôle: Mr. Richey and Dr. Thomas remark in the present volume that even the supposed minor share rests on slight evidence. There is said to be very little positive support to the origin of plateau basalts by fissure eruptions: and there are many features that require a different explanation (p. 52), and it is pointed out that in spite of the clearness of the cliff sections, "no undoubted case of a dyke feeding a lava flow has been recorded" (p. 52). The Ardnamurchan volcanoes are surrounded by circular dykes rising from the lava basin below. These ring cone dykes were first recognised in Glencoe by Messrs. Clough, Maufe, and Bailey, and have since been found in

Mull and Arran. The same structure is shown to be well developed in Ardnamurchan, which throws further light on this type of volcanic eruption. The intensely dissected volcanoes of western Scotland doubtless reveal the structure of the foundations of such great cone-volcanoes as Etna, in which the central crater is surrounded by a zone of large secondary craters that may be the outlets from ring dykes.

A second topic on which earlier views are vindicated by the present memoir is the extent to which rocks of different composition are combined by the absorption of material by a molten rock or the mixture of different rock magmas. Such composite rocks are known as hybrids and were described by Dr. Harker in his memoirs on Skye and the adjacent islands. The importance of these rocks was discredited by the survey of Mull. Dr. Thomas reaffirms the formation of true rock hybrids, and though his statements are cautious, they suggest that he regards these rocks as more important than has been recognised in some Survey memoirs.

Western Scotland is traversed by innumerable parallel dykes in groups known as swarms. The distribution of the four or five swarms in northern Britain and Ireland is shown in an instructive diagram (p. 52). The dykes in Coll belong to the Mull swarm and those east of Ardnamurchan to the Skye swarm. The dykes trend from north-west to south-east, except in the Southern Uplands of Scotland and the north of England, where they curve round to approximately west to east. Their number is so large that Dr. Tyrrell's measurements in Arran prove that the fissures into which these dykes were injected amounted to an eighth of the width of the area.

These dykes belong to all stages in the last Scottish volcanic period, though they were most numerous towards its end. Their distribution must have been controlled by some process that acted on a continental scale, and was probably due to the tensional rifting of the crust during the last great subsidence of the North Atlantic. Their parallelism to the Scottish sea lochs, as in Skye, indicates that those fiord-like valleys are due to the same process. The volume says little, however, about the physiography and glacial history of the area.

The Mesozoic sedimentary rocks of Ardnamurchan, the importance of which was first recognised by Judd, are fully described. Unfortunately, there is little such material associated with the lavas. A thin mudstone below them contains a shark's tooth derived from the Chalk, which probably once existed in the area. The few coaly beds add nothing to the evidence from Mull as to the age of the eruptions.

The Memoir contains many excellent illustrations and a geological map of the whole of Ardnamurchan, of which the eastern part lies in sheet 52 and has not yet been completely surveyed. This map, being somewhat diagrammatic, is more convenient in reference to the general history than sheet 51, which is more crowded and less clear. The Geological Survey and the authors are to be congratulated on the volume, which completes the series of monographs on the main Kainozoic volcanic centres of the Western Isles. J. W. G.

Formal Logic.

The Foundations of Mathematics: and other Logical Essays. By Frank Plumpton Ramsey. Edited by R. B. Braithwaite. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xviii + 292. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., 1931.) 15*s*. net.

FRANK PLUMPTON RAMSEY, recognised as a leader of Cambridge thought at the age of sixteen, died at the age of twenty-six. This volu contains his chief writings on logic and philosop about half of them unpublished, with a short app ciation by Prof. Moore and a longer one by editor; his work on economics, a secondary i terest, is represented only by a letter from Mr. Keynes to the editor. To those who knew him, the book will serve in some measure as a fitting memorial to his brilliant intellect and vivid personality; those of us who did not must judge it primarily as a contribution to learning.

Any attempted estimate by the number and importance of conclusions established would be quite misleading. In the field of very abstract thought in which Ramsey lived, to travel magnificently is more important than to arrive; the works of Ramsey's masters, of Whitehead and Russell and of Keynes, are universally acclaimed, although nobody — certainly not Ramsey — accepts their main conclusions. Moreover, Ramsey at his death was still in the stage when "calmness in infanticide" (to quote the editor) is a merit, and the certainties of to-day are the fallacies of to-morrow. The quality of the thought is what really matters.

Nevertheless, a brief summary of his work must be attempted. He was concerned in the main with two great classical problems, of which the first is indicated in the title. As is well known, Whitehead and Russell, following Frege, tried to exhibit pure mathematics as a branch of formal logic, and to show that all its results flow from the axioms that make consistent thought possible. They encountered two chief obstacles, one arising out of the nature of 'implication', the other represented by the famous contradictions. Ramsey, using the ideas of Wittgenstein, surmounts the first obstacle to his own satisfaction; but he can find no way of surmounting the second, except by introducing assumptions that are not completely self-evident. Since he rejects the view, dominant on the Continent, that another satisfactory basis for mathematics can be found, he seems driven to the conclusion that the part of mathematics in which the contradictions arise is not true. This conclusion, the editor tells us, he finally accepted, although acceptance would have involved much recantation. Since the rejected part is that involving the conception of infinite aggregates, he finds himself at last in accord with common sense.

The second problem is to find a meaning for 'probability', as a degree of belief, such that the mathematical theory of probability can be interpreted as a 'logic of consistency', related to partial knowledge as ordinary logic is to full knowledge. This problem inevitably leads to that of the relation between belief and truth. Ramsey's solution is to define a method of measuring belief by means of the odds accepted in betting; he can then show that the mathematical theory states rules that must be obeyed if betting is not to lead to certain loss, just as logic gives rules that must be obeyed if even true premises are not to lead to false conclusions. This view is less in accord with common sense; but it is wholly consistent with, and indeed inspires, his general philosophy, which is extremely pragmatic. Logic, he holds, is concerned only with consistency; it can lead to nothing not contained in the premises. Truth is determined by value in action; consistency in thought is a form of truth because it leads to consistency in action.

Ramsey admits that probability in this sense is not the probability of statistics or science; the paper on "Probability in Science", in which the connexion would have been described, was never written. But it is unlikely that it would have satisfied scientists; for Ramsey's philosophy, like that of most formal logicians, seems to leave no room for any distinctively scientific reasoning. He leaves to science the task of discovering truth; but induction, the process of discovering it, is not deduction, and is therefore nothing but a good habit. As for theories, his extremely difficult paper on this topic begins with the assumption that a theory is merely a new language. He seems to deny that there is any difference between scientific truth and falsity other than value in action.

This refusal to recognise any form of reasoning other than that of formal logic makes Ramsey's work curiously uneven. When he is discussing any problem amenable to formal logical treatment, he is extremely subtle and profound. But when he is not—and books about logic are mainly non-logical—his 'arguments' are chiefly an appeal to prejudice. He makes no real attempt to meet the views of those who differ from him fundamentally; he cannot have believed that Hilbert would have been seriously perturbed by his reasons for rejecting 'formalism'; and when he attempts a *reductio ad absurdum*, his absurdity usually seems to me the plain and sober truth. It is curious that modern logic, arising from the discovery that the Aristotelian syllogism is too narrow, should have stopped so short in removing its limitations. The difficulties that Ramsey discusses in the expression of facts by propositions are closely similar to those that puzzled the medieval logicians when they tried to express all arguments as syllogisms. But it never seems to occur to him that the limitation of reasoning to ordered propositions may be too narrow, and that his difficulties would vanish if he would investigate more closely the nature of 'facts'.

It is unlikely, therefore, that Ramsey's work will change the opinion of those who regard formal logic as an entertaining game, of value only to those who find interest in it. Even as an exponent of a game, he is not so attractive to amateurs as many of his predecessors. He lacks the graceful lucidity of the earlier Cambridge school. He was brought up to think in terms of the new symbolism; it is his natural language; between his formal logic and that of Russell there is all the difference between the French of the schoolroom and of the Parisian streets. Yet even those who cannot truly appreciate the importance of his work may join with those who can in deploring his early death as a great blow to British learning.

NORMAN R. CAMPBELL.

Plant Biochemistry.

The Principles of Plant Biochemistry. By Muriel Wheldale Onslow. Part 1. Pp. vii + 326. (Cambridge: At the University Press, 1931.) 16*s.* net.

THAT recently named branch of science, biochemistry, has grown within the last few years to such dimensions that no single worker can embrace the subject as a whole. Hence subdivision has become necessary. The two great branches of the subject are those devoted to plant and animal physiology. They are complementary, and one could not continue its existence without the other. The present volume, written by an investigator who has established a reputation by her researches in the subject, is the first part of a textbook intended for the student and for the beginner in research.

The book is divided into six chapters. That dealing with the sugars gives a useful summary of our knowledge, and the work of the leading authorities who have contributed to the biochemistry of the subject is cited. The statement on p. 59 that "sucrose is probably the chief sugar of translocation" is one that cannot be accepted. Sucrose is an intracellular reserve sugar. The hexoses are the translocation sugars. Numerous investigators are mentioned as having reported that maltose exists in foliage leaves, but their methods of estimating that sugar are open to criticism. Mrs. Onslow doubts the existence of maltose in the leaf and assimilating organs. Probably no reducing sugars of higher molecular weight than the monosaccharides occur in such organs of plants.

The belief is growing of the presence of the so-called γ-sugars in Nature, and the observation of F. F. Blackman is quoted that the sugars concerned in respiration are the γ-forms. Mrs. Onslow suggests that these labile forms are the first products of photosynthesis. She also suggests that starch and inulin may contain residues of these γ-sugars, and indeed there is some evidence that this is the case.

In the chapter on the "Cell Wall", celluloses, hemicelluloses, gums, mucilages, pectic substances, cutin, and suberin are dealt with. A scheme is outlined to explain the formation of the structural and reserve polysaccharides from the monosaccharides. Under gums and mucilages the greater part of the text is taken up with a description of the recent work of Norman. Spoehr's work, suggesting that in the formation of gums the high pentosan content is due to the oxidation of the hexoses, is referred to. It has long been known that some moulds growing parasitically on certain trees induce the formation of gums, and the late Marshall Ward in 1901 pointed out that the so-called 'gummosis' is a pathological phenomenon. The bacterial origin of gums was demonstrated by R. Grieg Smith in 1904. Reference to this work might have been expected.

No mention is made of the physics of the cell wall, but perhaps the author regarded this as extraneous. Overton's work, however, suggesting that the semipermeable character of the cell membrane is due to a lining of lipoid, might perhaps have been referred to. A concise account is given of our knowledge of oxidising and reducing systems and of respiration. The chapter on nitrogen metabolism is a well-written summary of our knowledge of a difficult and obscure branch of science.

A useful feature of the work is the very complete bibliography attached to each chapter. There can be no doubt that the author has achieved her object, and that she has produced a valuable and concise work on the principles of plant biochemistry.

ARTHUR R. LING.

The Chemical Engineer.

Elements of Chemical Engineering. By Prof. Walter L. Badger and Prof. Warren L. McCabe. (Chemical Engineering Series.) Pp. xvii + 625. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1931.) 25*s*. net.

WE believe the engineer began as a person responsible for the construction of engines of war; the profession has prospered and to-day there are all sorts of engineers, of which the latest is the chemical variety. For a time opinions differed as to his utility, his function, and his training, but clarity on these points seems to be forthcoming with the very rapid development of chemical industry, and the chemical engineer is settling down to become a very useful member of society. It has been recognised that there are many unit operations common to all chemical processes and even vital to many industries not ordinarily considered chemical. Such are the transportation of liquids, the flow of heat, evaporation, diffusion, distillation, humidifying, drying, gas absorption, extraction, filtration, and a few more.

In many manufactures it may be that not a single chemical reaction occurs; they consist of a series of unit operations such as the above. An engineer thoroughly trained and versed in all these unit operations will be of considerable value in industry. In this way a more definite line of demarcation of the chemical engineer from both the chemist and the engineer has been arrived at, and there is a movement on foot to train the student on the lines indicated. Industrial chemistry, which is concerned with individual processes as entities, is thus clearly differentiated from chemical engineering.

A committee of the American Institute of Chemical Engineering has attempted to set out the relative weighting of the several major subjects which should be taught; it is of interest that in a four-year course it gives 28 per cent to chemistry, 12 per cent to chemical engineering, and 14 per cent to other engineering. The book before us aims at teaching the 'elements' of chemical engineering along the lines indicated. It overlaps to some extent the pioneer work on the "Principles" by Walker, Lewis, and McAdams, which, however, is too advanced for beginners; so there is ample room for the work of Badger and McCabe. Both authors are so well known in their profession that there is no fear that they will have shirked their task. The book is blessed by A. D. Little, who contributes a very practical introduction containing much sound advice. If the chemical engineer will teach manufacturers, as Dr. Baekeland puts it, to "make their blunders on the small scale and make their profits on the large scale", then new inventions will be more often a source of profit to those who finance them. E. F. A.

Modern Views on Magnetism.

Magnetic Phenomena: an Elementary Treatise. By Prof. Samuel Robinson Williams. (International Series in Physics.) Pp. xxii + 230. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1931.) 15*s*. net.

THIS is the fourth volume of the series. The three which preceded it dealt with subjects in advanced physics. In the first of these, which discussed the most recent of the recent advances, it was a matter for thankfulness to find that the title "The New Physics" never once appeared. It is probably due to the much greater popular interest which is taken in scientific subjects in the present century, as compared with that taken in the past century, that the phrase has now come into very frequent use. Yet in the past century great and even revolutionary advances, without which the now recent advances could scarcely have matured, were made in physics. Nevertheless, these were spoken of with reticence as 'recent advances in physical science', though time has placed them as the greatest at that date since Newton's day. There is only one physics developing continuously as time progresses. Had Newton been asked if his Laws were observed in sub-atomic dynamics, he would very certainly have said that he had no data on which to found an answer. The universe of molar physics is entirely untouched by the discovery of the electron, and that is the main subject matter of elementary physics. Similarly, it is untouched by the quantum and by relativity. But the supposed inversion of all physics, which has been impressed on the popular mind, has induced an expectation of inverted textbooks.

A glance at Prof. Williams's textbook dispels fear on this point. The electron appears in a few sentences only; the magneton, even, in a page or two only; the quantum in one paragraph; and relativity not at all. Yet the book is thoroughly up to date and modern. The treatment is fresh. This appears even in the titles of chapters, and in their arrangement. 'Magneto-magnetics' instead of 'magnetism' may seem peculiar. That chapter occupies, as it ought, about half the book. 'Magneto-mechanics', 'magneto-thermics', etc., are expressive. The student who uses the book will find fresh breezes blowing through it, and will be led up to the mountain tops, or at least see them temptingly in the distance. It is a book for a learner who wishes to go far.

One sentence may be quoted: "There is no physical existence of these [magnetic] lines of force" (p. 6). Here the author is pointing out, quite necessarily, that there is no terminal magnetic charge corresponding to electric charge in the case of electric lines of force. But reference to the closed electric lines of force which surround the line of motion of a magnetic pole would be useful. Faraday and Maxwell regarded both sets as having real physical existence in the ether. Probably the author does so also; and so would Newton have done. Yet those mathematicians who pay attention to formalism alone, and those philosophers who pay attention to idealism alone, deny physical existence to the ether itself because it is not required for the expression of the formal relationships given in the modern physical equations. Newton's famous dictum, given by him as an *experimentalist*, *Hypotheses non fingo*, tends to be regarded as an absolute dictum applicable even to modern physical theory, and the abolishment of the ether. But Newton's dictum, given by him as a *theorist*, was this, "that one body may act upon another at a distance through a *vacuum*, without the mediation of anything else, by and through which their action and force may be conveyed from one to another, is to me so great an absurdity, that I believe no man who has in philosophical matters a competent faculty of thinking, can ever fall into it".

W. PEDDIE.

Short Reviews.

Anthropology and Ethnology.

Ethnos: or the Problem of Race considered from a New Point of View. By Sir Arthur Keith. (To-day and To-morrow Series.) Pp. 92. (London: Kegan Paul and Co., Ltd., 1931.) 2*s*. 6*d*. net.

Avowedly and of intention, Sir Arthur Keith in this little book has departed from the tacit understanding among anthropologists that they should not in any way trespass on politics; but, as he says, it is impossible to write about human races without touching upon matters which concern statesmen just as much as anthropologists. In fact, Sir Arthur, in hoping that he may induce politically-minded people to study the problems of race from an anthropological point of view, is doing no more than extend to international affairs that practical application of anthropology for which we have pressed in the administration of the dependent races of the British Empire.

In this essay, Sir Arthur has carried a little further the ideas he put forward in his Huxley Lecture to the Royal Anthropological Institute in 1928 and a subsequent public lecture before the Institute in 1929, and has applied them in principle to the problem of internationalism, in its relation to the future peace of the world. In Sir Arthur's opinion, every nation is a potential race, and a sense of nationality, or patriotism, has been one of the most potent of factors in the evolution of the races of mankind as they exist to-day. As race-consciousness is held to be largely responsible for our present troubles, this conclusion may seem pessimistic in so convinced an evolutionist as Sir Arthur; but he sees two possible solutions in either deracialisation by fusion into one race throughout the world, or a continuance of the evolutionary process through race, but under rational control. While Sir Arthur's views, therefore, are not without some comfort for struggling humanity, his more recent pronouncements suggest the inference that only the federally-minded are to survive.

Matriarchy in the Malay Peninsula and neighbouring Countries. By G. A. de C. de Moubray. Pp. ix + 292. (London: George Routledge and Sons, Ltd., 1931.) 15*s*. net.

Mr. de Moubray's book on the matriarchate in the Malay Peninsula illustrates a serious difficulty. Changes are taking place with such rapidity in modern conditions of contact between European and non-European civilisations that it is almost impossible for the inquirer to ascertain the truth in respect of many customs. The apparent inconsistency or inaccuracy may be due merely to recent changes; it is even possible that this statement of custom may never have been more than a semblance of the truth—in fact, it may resemble the idea laid up in Heaven in the Platonic sense. Thus, among the people of Negri Sembilan, with whom the author was more intimately concerned, inheritance was in the female line, and no male could hold land. Now, however, owing to the development of the rubber industry, land cleared and cultivated by the individual has come to be regarded as in the nature of any other form of personal property, and so may be held by the male.

Mr. de Moubray, in his inquiry into Malayan matriarchy, has obtained a great deal of evidence at first hand, valuable material, which is here printed in full. With the view of arriving at the underlying principles of the custom, he has been led to compare it with the matriarchal system in Menangkabau, the place of origin of part at least of the population of Negri Sembilan, Canara, and Malabar, where the Nayars still hold to it. His discussion of the social value of the matriarchal system in present conditions serves to emphasise once more the practical value of an inquiry of this nature for the work of administration.

Leitfaden der Anthropologie. Von Dr. K. Saller. Pp. iv + 284. (Berlin: Julius Springer, 1930.) 25·80 gold marks.

A brief note must suffice to direct attention to this excellent and much-needed textbook of physical anthropology. The treatment is comprehensive, each aspect, biological, morphological, palæontological, evolutionary, and so forth, being covered. Methods are fully explained, the exposition being accompanied by numerous diagrams, and the present position of our knowledge on the main questions outlined. The section on race is well illustrated by distinctive types, and some attention is given to the neglected question of cross-breeds and hybrids.

Biology.

One Touch of Nature: a Literary Nature Study Reader for Boys and Girls. Arranged by Dr. F. W. Tickner. Pp. viii + 187 + 7 plates. (London: University of London Press, Ltd., 1931.) 2*s*. 6*d*.

In these days of mechanism, when school books and teaching deal so much with the mechanical, it is a refreshing change to find such a book for children as "One Touch of Nature", written and compiled as it is from a varied selection of well-known, well-tried, and well-read Nature writers.

In arranging a volume of this type, for boys and girls, one must not overlook the fact that the average modern boy and girl is often more intrigued by, and interested in, the mechanical side of life. The importance of encouraging the younger generation in a closer and more intimate study of Nature is clearly described by William Warde Fowler on p. 137. In view of the delicacy with which a child's interest in Nature should be captivated and retained, to include such portions from the extracts of John Richard Jefferies as "Bevis and the

Wind" is to risk courting ridicule from the average schoolboy, whose interest in this book would centre rather round its nature study than its literary study.

The value of the book as a helping hand to readers would undoubtedly be greatly enhanced by illustrations and more photographs, and one is sorry to find so little reference to the commoner birds, such as the robin, thrush, and blackbird, which may usually be seen even by the city or town child.

Dr. Tickner wisely discloses the fallibility of Nature writers, a point which will tend to inspire the child with a desire to find out for himself. In passing, attention might be directed to the inferred contradiction as to the behaviour of the tortoise in rain.

"One Touch of Nature", though in places a little advanced for the average child-mind, is on the whole a delightful book, and should go far in helping its readers to observe things in the right way and then to describe concisely and clearly what has been observed and noted.

Fifty-two Years of Research, Observation and Publication, 1877–1920: a Life Adventure in Breadth and Depth. By Prof. Henry Fairfield Osborn. Edited by Florence Milligan. With Complete Bibliography, Chronologic and Classified by Subject, 1877–1929. Pp. xii + 160 + 9 plates. (New York and London: Charles Scribner's Sons, 1930.) 1.50 dollars.

HERE is a most impressive monument to the accomplishment of a great scientific worker. Osborn early found that "research is work of the hardest kind, requiring persistence, intelligence, and imagination", and all those qualities are necessary for a proper understanding of this skeleton of a life's work. Its main bulk is made up of a chronological and a classified list of the author's publications, 801 of them; of the share he has taken in the work of learned academies, revealed by lists of awards, degrees, and fellowships; and little space is left for a personal or intimate account of the great adventure. But the outstanding facts are clear.

The application of a two-edged discipline of detailed, intensive investigation, illumined by broad generalisations or hypotheses, has resulted, on one hand, in monographic researches on the rhinoceroses, horses, titanotheres, proboscideans, and reptilian sauropods, as well as in hundreds of lesser investigations. On the other hand, from the details have sprung a crop of 'principles', such as adaptive radiation or divergence, coincident selection, rectigradation or the predeterminate origin of new characters, allometrons or the adaptation of proportions in skull and skeleton. Osborn frankly admits that several of his principles have "gained no acceptance in the current realm of either biologic or palæontologic thought", but he is content to bide his time, believing that sound principles will finally gain universal acceptance, and that the less widely unsound ones are accepted the better.

J. R.

Chemistry.

Handbuch der anorganischen Chemie. Herausgegeben von Prof. Dr. R. Abegg, Dr. Fr. Auerbach und Prof. Dr. I. Koppel. In vier Bänden. Band 4, Abteilung 3: *Die Elemente der achten Gruppe des periodischen Systems.* Teil 2: *Eisen und seine Verbindungen.* A Lieferung 1. Pp. Axvi + A336. (Leipzig: S. Hirzel, 1931.) 40 gold marks.

THE present volume of this well-known treatise deals mainly with the physical properties of metallic iron. The atomic weight is also discussed. The spectrum, magnetic properties, crystalline form, thermal properties, electrical resistance, etc., are treated very fully, the numerical data being given in great detail. The preparation of pure iron, including electrolysis, and colloidal iron form the chemical part of the volume. The physical side is more prominently dealt with than in most of the preceding volumes of the series, and, for example in the sections on magnetism, it seems as though this aspect has been given too much prominence in a treatise on chemistry. It would probably be wiser in succeeding volumes to stress the chemistry more and to avoid expanding the series too much in the direction of pure physics, thereby adding to the size and expense to an unnecessary degree. The volume is a welcome step towards the completion of the excellent series and should be in all chemical libraries. The printing and paper are of the best quality.

The Modern Soap and Detergent Industry: a Complete Practical Treatise in Two Volumes on the Manufacture of Laundry, Toilet, Pharmaceutical, Textile, Abrasive, Scouring and Powdered Soaps. By Dr. Geoffrey Martin. Second edition, revised and enlarged. Vol. 1: *Theory and Practice of Soap Making.* Pp. xii + 76 + 37 + 34 + 53 + 13 + 100 + 64 + 4. Vol. 2: *The Manufacture of Special Soaps and Detergent Compositions.* Pp. xii + 102 + 40 + 26 + 50 + 16 + 35 + 38 + 6 + 37 + 31 + 51. (London: Crosby Lockwood and Son, 1931.) 36*s.* each vol.

THIS very practical and detailed treatise has been brought up to date by the author, and contains an account of all important recent advances and new patents in the soap industry. It covers British, American, and Continental practice and deals also with analysis and laboratory control. Dr. Martin's work is authoritative and will be welcomed by those interested in the soap and allied industries. It is fully illustrated and indexed.

A Life of Joseph Priestley. By Anne Holt. Pp. xviii + 221. (London: Oxford University Press, 1931.) 8*s.* 6*d.* net.

ALTHOUGH a good account of Priestley's scientific work has been given by Sir Edward Thorpe, there has been no adequate biography dealing with his many other activities. This need is, to some extent, supplied by the present work. The chapter on Priestley's chemical investigations is inadequate, but the author's intention was evidently to discuss in greater detail the personal life and the political and theological activities of Priestley, and she has made good use of the material available, some unpublished. The book covers the whole of Priestley's life, and in addition to making clear the great disadvantages under which Priestley carried out his scientific work, it provides a clear picture of the social life of his time. There is a useful bibliography.

Mathematics.

The Elementary Theory of Tensors: with Applications to Geometry and Mechanics. By Prof. Tracy Yerkes Thomas. Pp. ix + 122. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1931.) 10*s.* net.

The difficulties of the theory of relativity are much increased by the combination of unfamiliar physical ideas with the unfamiliar mathematical notation of the theory of tensors. Some universities are trying the experiment of separating these difficulties by giving an elementary course in tensors to undergraduates, with applications to ordinary geometry and dynamics.

Prof. Thomas's book is based on such a course given at Princeton University. After an introductory chapter recapitulating properties of determinants, it gives a brief chapter on the pure theory of tensors. Then follow three longer chapters, dealing respectively with the application to Euclidean geometry (emphasising the invariant point of view), kinematics (especially of the displacements and accelerations of a rigid body), and Newtonian dynamics (with a good deal about Lagrange's equations). The treatment throughout is such as to prepare the way for a study of Einstein's theory.

H. T. H. P.

Vorlesungen über Grundlagen der Geometrie. Von Prof. Kurt Reidemeister. (*Die Grundlehren der mathematischen Wissenschaften in Einzeldarstellungen mit besonderer Berücksichtigung der Anwendungsgebiete*, herausgegeben von R. Courant, Band 32.) Pp. x + 147. (Berlin: Julius Springer, 1930.) 11 gold marks.

This book is a comprehensive survey of the present conditions of the foundations of geometry. In the first part, the author follows Klein's programme of Erlangen, and discusses the notions of congruence and invariance, using freely the theory of groups, and giving an analytical treatment of generalised vectors without, however, employing determinants. But algebra is scarcely sufficient for an adequate description of the implications of space: geometry is more than a combination of numbers. So, in the second part of the monograph, the author gives an exposition of geometry as an autonomous axiomatic construction, discussing single systems of axioms with their logical characteristics.

The whole work is limited to plane geometry. On a point of method, however, it seems that a more rational presentation of such a difficult subject could be obtained by starting with axiomatic geometry.

T. G.

Introduction to Vector Analysis: with many Fully Worked Examples and some Applications to Dynamics and Physics. By L. R. Shorter. Pp. xiv + 356. (London: Macmillan and Co., Ltd., 1931.) 8*s.* 6*d.* net.

There is still considerable diversity of opinion concerning what amount of time students of mathematics and physics should devote to vector analysis, and at what stage it should be introduced. No one can doubt its value in advanced work such as differential geometry or electrodynamics, but it is still an open question whether it should be introduced to students of elementary geometry, mechanics, and physics. Many years ago, intermediate science students at the University of London were given a fairly full course in vectors, but now it is more usual to give only a very brief treatment, such as an introductory chapter to a textbook of physics. Mr. Shorter has come to the conclusion that this is unsatisfactory, as it does not give the grasp necessary to enable one to use the method with confidence. He therefore reverts to the older idea of supplying a complete elementary course. The distinctive feature of the book is the large number of fully worked examples. Those who can afford the time to study these should have a good grip of the subject.

H. T. H. P.

Metallurgy.

The Elements of Ferrous Metallurgy. By Dr. Joseph L. Rosenholtz. Pp. vii + 248. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 15*s.* net.

In view of the importance of the iron and steel industry to Great Britain, it is remarkable that so few textbooks are available to metallurgical students. One or two which formerly enjoyed a well-deserved reputation are now hopelessly out of date. The present volume comes from America, and the descriptions of plant relate to American works, but there is little which is not also applicable to English practice, and it is convenient to have the blast furnace, steel furnaces, and rolling mills well described and illustrated in a single volume of small size, whilst clear accounts are also given of such processes as tube-making.

The second part of the volume is occupied by an account of metallographic methods of study and of the constitution of iron and steel. This is excellently done, and the volume is to be recommended to students of engineering as well as of metallurgy. The chemistry of the various processes is simply and accurately explained. There are a few slips; the experiments suggested to the student on p. 15 could not be actually performed, and it will surprise Sheffield cutlery manufacturers to learn that shear steel cannot keep a cutting edge on account of its slag inclusions—these being the cause of the known great superiority of such steel for cutting. The illustrations have been drawn from other sources with good judgment, and well portray present practice.

The Metallurgy of Bronze. By H. C. Dews. (The Specialists' Series.) Pp. ix + 147. (London: Sir Isaac Pitman and Sons, Ltd., 1930.) 12*s.* 6*d.* net.

IN 1903, Heycock and Neville published their study of the copper-tin alloys, one of the classics of metallurgy, and the work of later investigators, which has filled in the gaps in their account, has only confirmed the accuracy of their diagram and their foresight in adopting long periods of annealing as a means of obtaining equilibrium. The bronzes are of great technical importance, and an account of their composition and uses, by a metallurgist accustomed to handling them in industry, is therefore to be welcomed.

This little book, high in price for its size, is well printed and contains the information most necessary to those who have to use bronzes for casting and other purposes. The term 'bronze' is taken in its proper sense, as meaning copper alloys in which tin is the principal added metal, but including complex bronzes, of which many now exist. There are some misprints, and the theoretical treatment of the subject is weak, the account of the iron-copper equilibrium on p. 84 being quite inaccurate. Most of the illustrations are good, but Figs. 9, 13, 14, 15, and 22 are merely black smudges, which is the more remarkable since these alloys give very clear structures when properly etched. The book will be of special use to foundrymen.

Impurities in Metals: their Influence on Structure and Properties. By Dr. Colin J. Smithells. Second edition, revised. Pp. xiii + 190 + 26 plates. (London: Chapman and Hall, Ltd., 1930.) 18*s.* net.

THE first edition of this book was well received by metallurgists, and a second has been called for. In addition to general revision, which has much improved the work, the subject of gases in metals has now been discussed in detail, mainly, however, in connexion with the non-ferrous metals. A fuller account of the state of knowledge concerning gases in steels, admittedly a controversial subject, would have been useful. The subject being the effect of impurities on the properties of metals, the section on magnetic properties might well have been expanded, in view of the enormous influence of even very minute quantities of impurity, of great theoretical significance as well as practical importance. Should another edition be required, the section on corrosion will also need expansion. The author's special acquaintance with tungsten enables him to illustrate several points by reference to that metal.

Metallurgists whose interest is in steel will be disappointed by the omission of many matters of importance to them which might have been included, but on the whole this attractively produced work will be found to contain a large amount of valuable information on a variety of metallurgical subjects.

Miscellany.

The Scientific Journal of the Royal College of Science. Vol. 1: containing Papers read during the Session 1930–31, before the Imperial College Chemical Society, the Royal College of Science Natural History Society, the Royal College of Science Mathematical and Physical Society. Pp. 158. (London: Imperial College Union, 1931.) 3*s.* 6*d.* net.

THIS publication, which appears as a result of collaboration between the three student societies named, may conceivably meet with criticism from some readers on the ground of redundancy, seeing that the substance of its most important papers can probably be found in print elsewhere. Others will discern in it a token of the vitality of the societies concerned. Moreover, it is apparent that a student journal of this type can fulfil an important service in broadening the interests of the members of each of the contributing societies. This result can only follow, however, if a judicious selection of the published papers is maintained: besides the more specialised papers, each section of the journal should contain at least one paper of general interest.

The first issue conforms to this criterion through the inclusion of instructive lectures on "The Life and Work of W. H. Perkin, Jun." (Prof. J. F. Thorpe), "Plant-Breeding" (Prof. F. L. Engledow), and "The Nature of Vowel and Consonant Sounds" (Sir Richard Paget). The biographical sketch of England's greatest organic chemist is full of interesting detail; and we cannot refrain from quoting a neat expression of a reflection which must occur frequently to all who experience the joys and sorrows of supervising organic chemical research: "It would appear, in fact, that these great manipulators possess some power which ordinary beings lack—some radiation from the eye, or some force which passes from them to the reaction vessel and compels the material to behave in the desired manner. Otherwise it seems impossible to account for the fact that compounds which in the hands of the ordinary research student remained, and would always remain, as an intractable gum, in Perkin's hands rapidly assumed the form of splendid crystals of undoubted homogeneity and purity." J. R.

An Outline of the Universe. By J. G. Crowther. Pp. xvii + 376 + 24 plates. (London: Kegan Paul and Co., Ltd., 1931.) 12*s.* 6*d.* net.

THIS brilliant and useful book deserves a warm welcome. The author describes it as the first attempt he knows in a new and necessary craft—"the conveyance of the atmosphere and facts of recent scientific research to the public, the conveyance of atmosphere being the more important part". He has certainly managed to compress into a smaller space the latest results in astronomical, physical, and biological science than any other writer we know; in fact, there is nothing quite like it, and Lord Rutherford's commendation is well deserved.

Mr. Crowther has divided the field into three approximately equal areas—the universe (in the astronomical sense), the atom, and life. On each of these he collects the latest and most striking scientific observations or theories, and ends with a short exhortation to mankind to emulate Nature and try to organise society as efficiently as Nature has organised the community of cells in his own body. That is the philosophy or moral of the book, so far as it has one, but the author certainly did not start with any philosophic purpose in mind. He is intensely interested in all the recent discoveries and is anxious that the educated public should share his interest.

Of the three main sections, that on life is the fuller and bears more trace of intimate personal knowledge and research. The astronomical section mostly follows the lines with which Sir James Jeans has made us familiar.

A word should be added on the abundant and most ingenious and suggestive illustrations. They could scarcely be better for the purpose in view.

F. S. M.

The Girdle of Chastity: a Medico-Historical Study. By Eric John Dingwall. Pp. x + 171 + 10 plates. (London: George Routledge and Sons, Ltd., 1931.) 10*s*. 6*d*. net.

IN this work, which forms an interesting companion volume to the author's study of male infibulation reviewed in these columns some years ago (NATURE, 97, 150; 1926), Dr. E. J. Dingwall makes a survey of the history and use of the girdle of chastity from the twelfth century down to the present day. Evidence is brought forward to show that the idea of the girdle of chastity is derived from that of female infibulation which originated in the East.

Seven types of girdles are discussed, the earliest being that described by Kyeser von Eichstadt in his military encyclopædia entitled "Bellifortis"; of which the MS. in the library at Göttingen is dated 1405, and the latest that devised by John Moodie, a Scottish doctor, as a means of preventing masturbation and seduction, and described by him in a work published at Edinburgh in 1848. A special chapter is devoted to the forensic aspects of the subject, and is followed by one dealing with the references to the girdle of chastity in belletristic literature from the fifteenth to the twentieth century. The text is illustrated by photographs and drawings of various girdles in different museums in Europe.

The author is to be congratulated not only for having produced a richly documented and very readable work, but also for continuing his valuable researches in the sexuological department of anthropology, which is still taboo to the great majority of the medical profession in Great Britain.

Philosophy.

Cosmic Problems: an Essay on Speculative Philosophy. By Prof. J. S. Mackenzie. Pp. ix + 122. (London: Macmillan and Co., Ltd., 1931.) 6*s*. net.

THE author of this book is not only a distinguished figure in the philosophical world, but also a teacher honoured by many hundreds of his former students. His power as a teacher, as well as a thinker, is manifest in all that he writes. He has the gift of making difficult matters seem at least not hopelessly incomprehensible. Indeed, he seems in some danger of sharing the philosophic fate of J. S. Mill, of whom it has been said that he made the mistake of writing clearly enough to be found out.

Throughout his career, Prof. Mackenzie has, as is well known, followed the line of idealistic speculation, and during that time there has not been, on the whole, much commerce between science and philosophy. But in these days, science has become philosophical, and some men of science, such as Whitehead and Russell, have become philosophers. Modern theories of evolution and of the spatio-temporal system are bound to be taken into account by speculative philosophy. In a series of short chapters, Prof. Mackenzie takes up one after another of the problems so raised, and tries to remove some of the difficulties in the way of a solution. For their complete removal, he says, the co-operation of the special sciences is required, and "happily there is now no real opposition between the results of the special sciences and the demands of speculative thought".

Orpheus: a History of Religions. By Salomon Reinach. Revised and partly rewritten. Translated by Florence Simmonds. Pp. ix + 487. (London: George Routledge and Sons, Ltd., 1931.) 15*s*. net.

THIS new and revised Anglo-American edition of M. Salomon Reinach's well-known history of religions, which in France has now reached its thirty-eighth edition, brings the survey of the religious movement in the modern world fully up to date. Here M. Reinach is amusing as well as instructive. In dealing with earlier times and other types of religion, the chapter on Christian origins has been almost entirely rewritten in the light of the fresh evidence furnished by the Emperor Claudian's letter to the Alexandrian community and by the Slavonic text of Josephus relating to Jesus, discovered some years ago and brought to the notice of the learned world in 1925. M. Reinach's interpretation of these two documents gives an entirely new conception of the course of events in Jerusalem leading up to the Crucifixion; for he concludes that the unnamed leader of the insurrection, which the text of Josephus states was in contemplation, was, in fact, Jesus.

Physics.

A Survey of Physics. By Prof. Frederick A. Saunders. Pp. x + 635 + 8. (London: G. Bell and Sons, Ltd.; New York: Henry Holt and Co., n.d.) 14*s*. net.

THE title of this volume is attractive, for it suggests a more interesting and readable account of physical phenomena and theories than is given in the ordinary textbook. This anticipation is realised in full measure, for Prof. Saunders of Harvard has been markedly successful in collecting novel illustrations of physical principles and in instilling the spirit of the scientific investigator. The gyroscopic ship-stabiliser, the diffusion or condensation pump, the Shortt clock, the internal combustion engine, the phonodeik and architectural acoustics, are a few of the titles attracting attention in the first half of the volume, and in the second half, dealing with electricity and light, the author revels in up-to-date applications of physical methods. Of particular interest and merit are the biographical notes scattered throughout the volume. These brief records of the leaders in physics, both ancient and modern, are well conceived and admirably executed; they are remarkably accurate, and our only regret is that they are not more numerous.

The book is designed for college students but "no great store of mathematical knowledge is required". In words which possibly reflect his own experience as a teacher, the author adds: "Beyond this the reader's equipment is supposed to include an inquiring mind, ordinary human powers of observation, and an average acquaintance with modern civilisation." Prof. Saunders is not afraid to introduce "the newer, and presumably better, conceptions usually referred to as 'modern' physics. These will prove useful and stimulating, perhaps at times even irritating." Towards the end of the book the reader is informed as to the emission of light in quanta, Bohr's theory of the hydrogen atom, wave mechanics, and finally the theory of relativity.

The book is well produced and well illustrated, and in its freshness and completeness can be confidently recommended to the general reader as well as to the teacher in search of new material. It is one of the best college textbooks yet provided by our American colleagues. H. S. A.

Wilhelm Conrad Röntgen und die Geschichte der Röntgenstrahlen. Von Dr. Otto Glasser. Mit einem Beitrag: *Persönliches über W. C. Röntgen,* von Margret Boveri. (Röntgenkunde in Einzeldarstellungen, herausgegeben von H. H. Berg und H. Frik, Band 3.) Pp. xi + 337. (Berlin: Julius Springer, 1931.) 29·60 gold marks.

In the autumn of 1895, Prof. Wilhelm Conrad Röntgen of Würzburg, Bavaria, discovered the rays which he called the 'unknown' or 'X' rays, but which are now frequently known by his name. In this book, Dr. Otto Glasser gives much miscellaneous information about his work, and Miss Margret Boveri, who was a friend of the great physicist, gives many interesting personal details of his life. An excellent photograph, signed 'Dr. W. C. Röntgen', forms the frontispiece, and there are many photographs of historic letters, documents, and skiagrams. A picture is given of the modest but attractive laboratory in the Physical Institute in Würzburg where Röntgen rays were first discovered. An excellent skiagram of a hand taken by Röntgen himself in Hamburg on Jan. 17, 1896, is shown. The development of Röntgen photography was extraordinarily rapid. Other skiagrams, taken in January 1896, are shown, including one by Campbell Swinton. In the appendix a list of 1044 communications to the press on the subject, published in 1896, is tabulated. Of these, twenty were written by Campbell Swinton, eight being published in NATURE. Lodge published fifteen and S. P. Thompson seven, several of which were in NATURE. A picture published in *Punch* on Jan. 25, 1896, shows that the new photography has its humorous side. A long list, but far from complete, of the well-deserved honours received by this great physicist in his lifetime is given. It includes the Rumford Medal of the Royal Society in 1896 and the Nobel Prize in 1901. His letters show that in his private life he was a modest and lovable man. The book would be improved if it had an index.

Electricity and Magnetism: an Advanced Text-book for Colleges. By Prof. Charles A. Culver. Pp. viii + 383. (New York: The Macmillan Co., 1930.) 14*s.* net.

THIS book sets out to give a reasonably complete presentation of the fundamental principles upon which rest the everyday applications of electricity and magnetism. Its standard is somewhat higher than that styled 'intermediate' in Great Britain, clear accounts of the elementary principles of alternating currents and thermionics being included. The author has also made an attempt to give an up-to-date and simple description of the earth's magnetic field, and throughout the book emphasis has been placed on the practical applications of physics. The diagrams are very good, but some of the photographic reproductions could be improved. Why is it that nearly all publishers appear content to reproduce X-ray photographs in a manner which gives an utterly false impression of the radiographer's work with modern apparatus? When a new edition is called for, the exceedingly poor skiagraph of a human skull should be omitted, if not replaced by a more satisfactory picture.

La synthèse des ondes et des corpuscules. Par Karl K. Darrow. Exposé élémentaire publié avec une introduction et des notes par Marcel Boll. Pp. 54. (Paris: Hermann et Cie, 1931.) 10 francs.

THIS booklet is a translation of one of the admirable articles contributed to the *Bell System Technical Journal* by Karl K. Darrow. The fact that foreign publishers consider these articles sufficiently important to warrant translation, indicates that English readers would do well to consult them. The article before us is an extremely instructive explanation of certain simple optical and electron phenomena, such as diffraction by a grating, on the basis of the corpuscular and undulatory theories. In it, the author shows how recent work has so modified our conceptions that we now look upon corpuscles and waves, not as two alternatives between which we must choose, but as complementary aspects of the truth.

Physiology.

Ephedrine and related Substances. By K. K. Chen and Carl F. Schmidt. (Medicine Monographs, Vol. 17.) Pp. v + 121. (London: Baillière, Tindall and Cox; Baltimore, Md.: Williams and Wilkins Co., 1930.) 11*s.* 6*d.* net.

IN the course of the last few years numerous papers have been published on the clinical use of ephedrine and it now has a definite place in therapeutics.

Although it may be considered by some a modern drug, yet the clinical use of the plant from which it is isolated dates back some 5000 years; and thirty-five years elapsed between its isolation and the discovery of its real value.

Ma Huang has been used in China by native physicians for thousands of years, and similar species of *Ephedra* have been employed as medicines in many other parts of the world since remote antiquity. It was not until 1885, however, that Yamanashi obtained an impure crystalline substance from the plant. Two years later, Nagai and Hori isolated the alkaloid in pure form. Miura found that the alkaloid was toxic in large doses, but advocated its use as a mydriatic. Its clinical value was not appreciated until 1917, when Amatsu and Kubota reinvestigated its properties; but their work passed unnoticed by the western world until 1923, when Chen and Schmidt began their researches.

The alkaloid ephedrine finds its chief use as a substitute for adrenalin, to which it is related in chemical structure; it is not so potent a substance, but it has the great advantage that it can be given by mouth. The authors describe in detail the actions of the drug on animals and its uses in the treatment of a variety of diseases in man. They also include a section on synthetic ephedrine and other related compounds.

The monograph gives a good though brief account of the work which has been carried out on the alkaloid during the past six years. Its perusal raises the question whether other valuable drugs may not be awaiting extraction from the herbs used by native physicians of the East.

The Metabolism of Tumours: Investigations from the Kaiser Wilhelm Institute for Biology, 'Berlin-Dahlem.' Edited by Otto Warburg. Translated from the German edition, with accounts of Additional Recent Researches, by Dr. Frank Dickens. Pp. xxix + 327 + 5 plates. (London: Constable and Co., Ltd., 1930.) 40*s*. net.

THE work of Otto Warburg on the metabolism of tumours is so well known that it needs no introduction; but for investigators working on the metabolism of isolated tissues, frequent reference to his methods and results is a necessity, so that the publication of an English translation will be widely welcomed.

Apart from a short introduction on the technical details of methods, the book consists of reprints of papers published since 1908 by Warburg and his co-workers. The earlier papers deal with the oxidation process in sea urchin eggs and red blood cells; from 1923 onwards the researches deal chiefly with tumour tissues. The metabolism of a tumour cell is characterised by the production of lactic acid in the presence of oxygen or aerobic glycolysis; normal tissues produce the acid in the absence of oxygen, but in its presence it is further oxidised; in other words, normal tissues obtain their energy by respiration, tumour tissues by the conversion of carbohydrate to lactic acid. The distinction between the two types, however, is not absolute: thus, tumours respire as well as showing aerobic glycolysis, whilst normal tissues can be made to develop the abnormal form of metabolism by interfering with their respiration. If a normal growing cell glycolyses aerobically, it usually dies; if it lives, a tumour results: hence, interference with the respiration in growing cells is the cause to tumours.

The English edition has been brought up to date by the inclusion of a few recent papers which were not in the German edition; it should prove of interest to a wide circle of readers.

Psychology.

Alcohol and Behaviour. By Prof. Sydney Smith. (The Henderson Trust Lectures, No. 10, delivered at the University of Edinburgh, 28th November 1930.) Pp. 37. (London and Edinburgh: Oliver and Boyd, 1930.) 6*d*.

IT is very refreshing to read a lecture on alcohol without finding any bias or the influence of vested interest as is so often the case in articles of this kind. Prof. Smith, in "Alcohol and Behaviour", the Henderson Trust Lecture for 1930, has presented as impartial a study of the subject as we could wish for. There are some most interesting, and at the same time most surprising, statements. We would scarcely expect to find that there is no relation between alcohol and the murder rate, that, despite the fact that drunkenness has diminished to such an extent, yet there is an increase in offences of a sexual nature up to twice the 1909 level, and that offences against property have considerably increased in the same period. It is also surprising to read that the expectation of life in those more than thirty years of age is not in any degree impaired by the moderate consumption of alcohol. The author concludes by reminding us that as a nation we are becoming year by year more sober, but at the same time more dishonest and less moral.

Crime as Destiny: a Study of Criminal Twins. By Prof. Dr. Johannes Lange. Translated by Charlotte Haldane. Pp. 199. (London: George Allen and Unwin, Ltd., 1931.) 6*s*. net.

PROF. LANGE attempts to show that in monozygotic twins there is a very strong tendency for one child to be a criminal if the other one is. We are not inclined to agree necessarily as to the "dreadful influence" of alcohol in creating criminals, nor do we agree that criminal tendencies are so largely the result of hereditary factors. The influence of bad environment and evil influence in childhood is of so much more importance. Much more can be done with problems of the young delinquent by means of child guidance than by any questions of sterilisation or the prevention of cross-breeding of inferior or criminal types.

Forthcoming Books of Science.

Agriculture, Forestry and Horticulture.

Baillière, Tindall and Cox.—Baillière's Encyclopædia of Scientific Agriculture, edited by S. H. Hunter, 2 vols. *Oxford University Press.*—Forestry Memoirs, No. 13: Regional Survey and its Relation to Stock-taking of the Agricultural and Forest Resources of the British Empire, R. Bourne; Historic Farms of South Africa. The Wool, the Wheat, and the Wine of the Seventeenth Century, Dorothea Fairbridge.

Anthropology and Archæology.

George Allen and Unwin, Ltd.—A Handbook of Classical Mythology, G. Howe and G. A. Harrer; The Evolution of Culture, J. Lippert, translated and edited by G. P. Murdock. *Edward Arnold and Co.*—The Psychology of a Primitive People: a Study of the Australian Aborigine, Prof. S. D. Porteous. *Macmillan and Co., Ltd.*—The Lakhers, N. E. Parry, with an Introduction and Supplementary Notes by Dr. J. H. Hutton. *Methuen and Co., Ltd.*—Egyptian Antiquities in the Nile Valley: a Descriptive Handbook, Dr. J. Baikie. *Oxford University Press.*—Roman Britain, R. G. Collingwood. *G. Routledge and Sons, Ltd.*—The History of World Civilization, from Prehistoric Times to the Middle Ages, Prof. H. Schneider; Sorcerers of Dobu: the Social Anthropology of the Dobu Islanders of the Western Pacific, R. F. Fortune, with an Introduction by Prof. B. Malinowski; Growing up in New Guinea: a Comparative Study of Primitive Education, Margaret Mead; Sexual Life in Ancient Greece, H. Licht; A Bibliography of Sex Rites and Customs, R. Goodland. *Charles Scribner's Sons.*—Tara: the Pagan Sanctuary of Ancient Ireland, Prof. R. A. S. Macalister; The Temple of the Warriors, E. H. Morris; The History of the Maya, from the Earliest Times to the Present Day, T. Gann and J. E. Thompson.

Biology.

George Allen and Unwin, Ltd.—The Life of Mendel, H. Iltis, translated by Eden and Cedar Paul; The Life of the Butterfly, F. Schnack, translated by Winifred Katzin; The Experimental Analysis of Development, Prof. B. Dürken, translated by H. G. and A. M. Newth. *D. Appleton and Co.*—The Insect Menace, Dr. L. O. Howard. *Baillière, Tindall and Cox.*—International Address Book of Botanists: being a Directory of Individuals and Scientific Institutions, Universities, Societies, etc., in all parts of the world interested in the study of botany. *Ernest Benn, Ltd.*—A History of Fishes, J. R. Norman. *A. and C. Black, Ltd.*—The Birds of the Air, or, British Birds in their Haunts, A. W. Seaby. *Cambridge University Press.*—Chemical Embryology, Dr. J. Needham, 3 vols.; Invertebrata: a Manual for Students, Dr. L. A. Borradaile, F. A. Potts and J. T. Saunders. *Chapman and Hall, Ltd.*—Oceanography, Dr. H. B. Bigelow. *J. and A. Churchill.*—Recent Advances in Botany, E. C. Barton-Wright. *W. Heffer and Sons, Ltd.*—Emigration, Migration and Nomadism, by the late Walter Heape, edited, with a Preface, by Dr. F. H. A. Marshall. *Methuen and Co., Ltd.*—Problems of Relative Growth, Prof. Julian S. Huxley; Microbes and Ultramicrobes: being an Account of the Bacteriophage in its Relations to Bacterial Variation and the Invisible Viruses, A. D. Gardner; Mendelism and Evolution, E. B. Ford; The Great Biologists, Sir J. Arthur Thomson; Plant and Animal Life: an Introduction to the Study of Biology, Rosamond F. Shove; The Teaching of Biology: a Handbook for Teachers of Junior Classes, Ethel M. Poulton. *Oxford University Press.*—Selecta Fungorum Carpologia of the Brothers L. R. and C. Tulasne, translated into English by W. B. Grove, edited by Prof. A. H. R. Buller and C. L. Shear, 3 vols.; Iconum Botanicarum Index Londinensis, G. A. Pritzel, Vol. 6: Saponaria-Zymum, with Emendanda; an Introduction to the Study of Vertebrate Zoology, based chiefly on the titles in the Blacker Library of Zoology, The Emma Shearer Wood Library of Ornithology, the Bibliotheca Osleriana, and other Zoological Collections of McGill University, Montreal, Canada, compiled and edited by C. A. Wood; West African Botany, F. R. Irvine. *Sidgwick and Jackson, Ltd.*—The Biology of Mammals, Prof. J. Ritchie (Biological Handbooks); The Principles of Animal Genetics, E. B. Ford; Experimental Zoology, Prof. Julian S. Huxley; Invertebrate Zoology, Prof. W. Garstang (Text-Books of Animal Biology). *University Press of Liverpool.*—L.M.B.C. Memoirs, No. XXX.: Manx Algæ: an Algal Survey of the South End of the Isle of Man, Dr. Margery Knight and Mary W. Parke. *Williams and Norgate, Ltd.*—Genetic Principles in Medicine and Social Science, Prof. L. T. Hogben; The Essentials of Bacteriological Technique, F. R. Hunwicke; Scientific Riddles, Sir J. "momentum of the system" to explain his observations on the behaviour of the motor neurones of spinal reflexes.

RUMOURS have persisted that a remnant of the once large herd of European bison which inhabited the Caucasus had survived the period of the War and the succeeding days when the herd proper was slaughtered for food by the distressed people of the district. In the early part of 1931, according to a bulletin issued by Science Service (Washington, D.C.), a Russian zoologist, M. Schaposnikov, set out to discover the truth or otherwise of these rumours, and his failure to report progress or to return has suggested that he may have fallen a victim to bandits. In the absence of any wild representatives of the European bison (or wisent), the only survivors consist of specimens in zoological gardens, and these at the beginning of the present year numbered sixty-one—thirty-two cows and twenty-nine bulls, including six calves born during 1930. During 1931, one bull calf and two heifers were born, but one of the heifers died. In addition, there exist a number of hybrid animals, the results of crosses with the American bison, but these, of course, cannot be reckoned in a wisent count.

IN many districts in England and Scotland the national grid of high-tension wires is now very conspicuous. In the Faraday centenary number of the *Times*, published on Sept. 21, Mr. P. V. Hunter points out that soon the subsidiary systems connected with it, operating at 30,000, 11,000, and 400 volts, will, so far as capital cost and magnitude of operations are concerned, be even more important than the grid itself. The British grid operates at 132,000 volts, and differs from similar networks abroad mainly by its very high factor of safety mechanically and the unusually high lattice towers used when it spans navigable estuaries. Mr. Hunter points out that there would be many advantages if underground cables were used for the subsidiary systems operating in agricultural and rural districts. These cables would not need to be armoured or otherwise carefully protected against accidental damage by other excavators, as they have to be in cities and in urban districts. He computes that if their cost does not exceed fifty per cent that of overhead conductors, then from the commercial point of view they would be more desirable. The better service, the better voltage distribution, the longer life, and the lower maintenance cost of the cables will more than offset their increased capital cost. The oil-filled cable which is being tried in certain situations is, at least as at present developed, of limited application, on account of the difficulties and expense of the necessary auxiliary equipment, especially where parts of the cables are at different levels. With our present knowledge it should not be difficult to make a cheap cable suitable for rural districts. As the great bulk of the lower pressure distribution systems have yet to be constructed, it is to be hoped that such cables will soon be forthcoming.

THE fortieth Annual Report of the Royal Society for the Protection of Birds makes an appeal for the clearing off of the debt still remaining upon the Romney Marsh Sanctuary. The step taken in the purchase of 140 acres of Romney Marsh was the direct answer—the only practical answer from England so far as is apparent—to the findings of the International Conference for the Protection of Migratory Wildfowl, held in 1927. At this conference a recommendation was made that there should be established in all countries winter sanctuaries where wildfowl might obtain a respite from constant pursuit and persecution. The Society, inspired by the recommendation, secured an excellent and varied area in Romney Marsh, the nucleus of which was purchased in 1928, but expenditure is required for the preparation of the land, for the provision of further cover for the birds, and for protecting boundaries. Up to the end of 1930, £1455 had been contributed in special donations, a considerable sum has been allocated from the general account (shown in the Report as £1995), but a sum of £639 is still required to meet the overdraft at the bank. The Society carries on an inestimable work on behalf of British bird life—its expenditure for 1930 on behalf of watching, lighthouse protection, oil pollution, and education amounted to £2230—and we commend the final appeal for the Romney Marsh Sanctuary to all bird-lovers.

IN the *Westinghouse International* for August, H. E. Dralle points out that there is great scope for the use of electricity as a motive power in the development of the Rumanian oilfields. Owing to the lack of transport facilities, development there was very slow before 1900. Many of the wells are thousands of feet deep, and so, although labour is very cheap, the cost of drilling them is high. Owing to the sandy nature of the soil, a successful method of pumping has not yet been invented and bailing is in general use. At some of the wells either flowing or being bailed, it is a common sight to see from four to sixteen people (men and women) standing up to their knees in pits of oil and cleaning away the huge quantities of sand that are brought up with the oil. When electric power is used for the drilling systems, it is necessary, owing to the presence of large quantities of inflammable gas, to use apparatus that makes no sparks or has been made gas-proof. For this reason also, the boilers which supply the wells with steam are located at least 2000 feet away from the nearest well. Transmitting steam at this distance at a pressure of 100 lb. per sq. in. presents many difficulties. At the present time the oil transportation is mainly by tank motor-car. Owing to the cost of the necessary electric pumping stations, it is doubtful whether pipe lines would be economical.

THE weather in England is a perpetual subject of interest, but nothing can give such substance to its consideration as the scientific correlation of its vagaries with the progress of plant and animal life in these islands. The Phenological Report for 1930 of the Royal Meteorological Society, therefore, is a very welcome document. The official verdict of 1930 is that it was a "wet year", and vegetation in general was a little later than the average for the past thirty-five years.

Apparently similar climatic conditions spread beyond the British Isles, else how can we account, to take one of the sets of phenomena discussed in the Report, for the late arrival of spring immigrants amongst birds, which cannot be seriously affected by conditions at the end of their migratory journey. A comparison of the lines of equal arrival dates of twenty species of birds in 1930 with those of the preceding year, shows that on the south coast of England arrival was delayed for three days, and that this delay affected the movements of the birds even to the north-east of Scotland, where a delay of the same period was noted. In both years, therefore, the progress of migration within these islands, from the Channel coasts to northern Aberdeenshire, occupied fifteen days, although it was almost a week later before the migrants penetrated to the inland districts. A new chart appears in the Report, showing the autumnal isophenes of the departure of the swift, swallow, and house-martin and arrival of the fieldfare and redwing, and this indicates a slower through-country movement, covering thirty days. Thus definite records substantiate a distinction which has been recognised in a general way between the characters of the spring and autumn migrations of birds.

IN a series of five illustrated articles in the *Engineer* from July 31 to Aug. 28, a review is given of modern methods of geophysical surveying. The subject is dealt with under the headings: the magnetic method, the gravitational method, electrical methods, and the seismic method. The theory of each method is discussed, the instruments used are described and illustrated, and some examples are given of successful geophysical surveys. Discussing the relative uses and application of the various methods and the place that they must take in physics and geology, the writer says the magnetic method finds a place in the equipment for any kind of geophysical surveying owing to its rapidity, but used alone the results obtained are sometimes of doubtful value, largely owing to the fact that the magnetic properties of materials are not so completely understood as are the properties made use of in other methods. The gravitational method suffers more than any other from the influence of topographical features, but it has the advantage that its theory is well understood. Electrical methods suffer from the disadvantage that the strength of the electrical indications falls off with disconcerting rapidity with increase of the depth explored, and are suitable for detailed investigations rather than large-scale surveys. On the other hand, the seismic method is well suited for large-scale survey, and is particularly valuable where stratification exists. It has been used with great success for the discovery of salt domes in the neighbourhood of which oil is to be found, and has been used extensively in America and by the Anglo-Persian Oil Company, Ltd.

IN ancient Indian carvings may be found represented a beast called by Sanskrit writers the water-elephant; this is depicted as a creature with the fore-parts of an elephant and the hind-parts of a fish, and might pass as a purely imaginary creature were it not for the fact that there are no tusks or ears, that the dentition given is that of a carnivore, with the characteristic canines, and that the trunk is abnormally short. These peculiarities suggest that the carvings are a rude attempt to portray the sea-elephant or elephant seal, which may once have ranged, if only occasionally, as far north in the Indian Ocean as it does in the Pacific to-day. At any rate, one of the diving-petrels—southern ocean birds which are not long-distance flyers—was believed to have been seen in Indian waters a century ago by Sundevall, and in our time by the writer of the present note; and in the *Field* for Aug. 22 (p. 300), G. Dickson, of Cape Town, publishes a photograph of what the editor very properly says is a young sea-elephant, taken at Cape Point. The suggestion is made that it had escaped from captivity, but the species is very rare in that condition, and, in view of the archæological evidence given above, a natural occurrence is at least possible.

PROF. WILLEM DE SITTER, director of the Leyden Observatory, was elected an honorary member of the American Astronomical Society at the recent meeting at the Perkins Observatory, Delaware, Ohio. The Society has elected the following new officers: *President*, W. S. Adams; *Vice-President*, C. G. Abbot; *Councillors*, J. C. Hammond, P. W. Merrill, H. H. Plaskett. Benjamin Boss was re-elected treasurer, and R. S. Dugan, secretary.

HAVING reached the statutory age for retirement, Mr. H. A. Hunt has retired from the position of meteorologist to the Commonwealth of Australia. Mr. W. S. Watt has been appointed his successor as from April 23, 1931.

DR. C. B. BRIDGES, of the California Institute of Technology, Pasadena, will give an address on "Genic Balance and Related Problems" at a meeting of the Genetical Society, to be held in the rooms of the Linnean Society at Burlington House at 3.30 P.M. on Oct. 19.

THE R.R.S. *Discovery II*, which was visited by many members of the British Association while she lay at St. Katherine's Dock, Tower Bridge, left on Oct. 3 for the Antarctic. The cruise is expected to last two years, and the work to be carried out will be mainly a continuation of the scientific investigation of the whaling industry.

ON Oct. 5, two American airmen, Mr. Herndon and Mr. Pangborn, completed a flight of 4465 miles across the Pacific Ocean from Sabushiro Beach, Japan, to Wenatchee, Washington. This is the first non-stop flight from Japan to the United States, and was accomplished in 41 hours 13 minutes.

THE opening meeting of the session of the Institution of Automobile Engineers took place at the Royal Society of Arts on Oct. 1. After Sir Herbert Austin had introduced Mr. W. A. Tookey, the president for the session 1931–32, to the chair, he was presented by Mr. Tookey with a commemorative certificate and badge. Mr. Tookey then delivered his presidential address, entitled "The Internal Combustion Engine and its Performance ". The Crompton Medal, which is awarded annually by the Council of the Institution of Automobile Engineers for the best paper read before the Institution during the session, has been awarded for the session 1930–31 to Dr. S. J. Davies and Mr. E. Giffen, of King's College Engineering Department, for their paper entitled " Injection, Ignition, and Combustion in High Speed, Heavy-Oil Engines ".

SIR WILFRED GRENFELL, in an article in the *Times* for Sept. 14, directs attention to the uncharted state of the greater part of the coast of Labrador. The coastal waters have been frequented by fishing boats for cod for many years, and, nevertheless, the charts are so inadequate that north of Cape Harrison they are, according to Sir Wilfred Grenfell, no use whatever to the navigator who has no personal knowledge of the coast. An aerial survey is now in progress, and the American Geographical Society is bearing the cost of constructing the map from the negatives. The British Admiralty is to begin surveying the coastal waters next year, so that before long this gap in the survey of the Empire will have been filled.

MR. H. V, GARNER, guide demonstrator of the Rothamsted Experimental Station, and other members of the staff of the institution are offering their services during the forthcoming winter in giving lectures to chambers of agriculture and horticulture, farmers' clubs, farm workers' associations, agricultural societies, etc., on the Rothamsted experiments. No fee will be charged for such lectures; but any association arranging such engagements must defray all expenses of the lecturer. Mr. Garner is offering several subjects, dealing chiefly with various forms of manuring. Subjects offered by other lecturers are: soil micro-organisms, Dr. H. G. Thornton, Mr. D. W. Cutler; agricultural botany, Dr. Winifred Brenchley; agricultural chemistry, Dr. E. M. Crowther, Dr. H. L. Richardson; soil physics, Dr. R. K. Schofield, Mr. G. W. Scott Blair; entomology, Dr. H. F. Barnes, Mr. D. M. T. Morland; mycology, Dr. W. B. Brierley, Dr. J. Henderson Smith, Dr. J. Caldwell, Mr. R. H. Stoughton. All communications regarding lectures should be addressed to the Secretary, Rothamsted Experimental Station, Harpenden, Herts.

THE Society of Glass Technology, with the support of the Glass Research Delegacy, is arranging an exhibition to illustrate the development of glass technological research in modern times. The exhibition, which is being accommodated in the Science Museum, South Kensington, London, will be opened by Sir Richard Gregory on Oct. 21, and will probably remain open until at least the end of November, and if possible, until the close of the year. Glass demonstrating the best chemical and physical properties for optical, illumination, electrical, mechanical, and artistic purposes will be shown. Processes in glass-works will be illustrated by photographs and specimens. A series of lectures on various kinds of glass is being arranged for Thursday evenings.

THE *Proceedings of the South London Entomological and Natural History Society* for 1931–32 contain, as usual, besides the reports of meetings, several articles of interest. Mr. H. M. Edelsten writes on the British species of *Nonagria* and their habitats, while Mr. A. E. Tonge contributes an article on the ova of many of the British Lepidoptera, illustrated by three excellent photographic plates. In his address, as retiring president of the Society, Mr. C. N. Hawkins deals with numerical variation in the ecdyses of lepidopterous larvæ, and collects together in convenient compass a good deal of data on the subject. We note from the treasurer's report for 1930 that the financial position of the Society is sound, with a substantial balance carried forward.

Two years ago the Division of Plant Industry of the Australian Council for Scientific and Industrial Research commenced a compilation of known Australian fungi (pathogenic and saprophytic), the work being carried out by Mr. C. C. Brittlebank, formerly mycologist to the Victoria Department of Agriculture. No systematic list had been prepared since 1895, when Mr. D. McAlpine recorded 2284 species and 415 hosts. The new catalogue contains more than 56,000 references to literature recording 6078 distinct species (with nearly 5000 synonyms) and 1343 hosts. State Government departments and universities in Australia have co-operated in its preparation, and material assistance has been given by the Imperial Institute of Mycology, Kew. The catalogue will now be kept up to date and should prove very useful to mycological investigators.

THE chapter on plant virus diseases from vol. 7 of " A System of Bacteriology in relation to Medicine ", published by the Medical Research Council of the Privy Council (see NATURE of Feb. 21, 1931), has been issued in pamphlet form. The article is by Dr. J. Henderson Smith, of the Rothamsted Experimental Station, and although only twelve pages in extent, it gives a remarkably full account of our present knowledge of these maladies. The economic damage caused by virus diseases is mentioned, and a comprehensive description of symptoms is given. Cytology, ætiology, and the various characteristics of virus extracts are dealt with, and considerable space is devoted to descriptions of transmission and specificity. It is interesting to note that even at the end of 1928, virus diseases had been reported on 264 species of plants. Many new diseases have been described since then, and it seems that the science of ' virology ', as some workers term it, will eventually rank with bacteriology and plant pathology.

MR. R. S. Frampton, 37 Fonthill Road, N.4, has sent us a copy of his catalogue (No. 65) of books, nearly a thousand in all, on natural history subjects. The prices asked appear very reasonable.

A LIST (No. 188) of some 432 second-hand works dealing mainly with floras of Europe, Asia, Africa, America, and Australia has just been issued by Messrs. Dulau and Co., Ltd., 32 Old Bond Street, W.1, and is worthy of perusal.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Doppler Effect in Light-Scattering.

IT is a problem of great interest to consider the changes in spectral character of monochromatic radiation resulting from the thermal agitation of a medium in which it is scattered. If we regard the subject classically, the result to be expected is obvious: there should be a Doppler broadening of the incident spectral line, varying with the angle of observation, and determined by the Maxwellian distribution of velocities of the molecules which scatter the light. It can readily be shown that, except in respect of the total intensity of scattered light, it would make no difference to the argument by which this result is deduced whether the molecules are loosely distributed as in a gas or are closely packed together as in a dense vapour or liquid.

It is very remarkable, however, that a wholly different result was deduced by L. Brillouin,[1] following the idea that the medium which scatters the radiation can be treated as a continuum filled with moving sound-waves of various wave-lengths which reflect the light-waves much in the same way that a moving crystal would give Bragg's reflection of X-rays. Brillouin's theory indicates that in the spectrum of the scattered rays the single line which represents the incident light should be replaced by a close doublet, the frequency shifts of which are given by the formula $\Delta\nu/\nu = \pm 2a/c \sin \frac{1}{2}\theta$, where a and c are the velocities of sound and light respectively, and θ is the angle of observation; the incident line itself would be missing in the scattered light. Brillouin's deduction of this formula has outwardly the appearance of being based on classical ideas. Actually, however, the argument ignores the existence of discrete molecules in the medium, and the results to which it leads cannot be reconciled with the classical point of view, according to which the incident line should persist in the scattered light in the same position with no change except a Doppler broadening.

The paradox presented above is resolved if we adopt the following view of the matter based on quantum principles. In a medium scattering light we are dealing with an assemblage of photons having energy $h\nu$ and momentum $h\nu/c$, material particles having translatory energy $\frac{1}{2}Mv^2$ and linear momentum Mv and also associated with the latter, quanta of sound, having energy $h\nu_s$ and linear momentum $h\nu_{s/a}$. The result of an individual encounter must satisfy the equations of the Compton type:

$$\tfrac{1}{2}Mv^2 + h\nu_s + h\nu_l = \tfrac{1}{2}Mv'^2 + h\nu'_s + h\nu'_l$$

$$\overrightarrow{Mv} + \overrightarrow{h\nu_{s/a}} + \overrightarrow{h\nu_{l/c}} = \overrightarrow{Mv'} + \overrightarrow{h\nu'_{s/a}} + \overrightarrow{h\nu'_{l/c}}.$$

The first is a scalar and the second is a vector equation. We obtain Brillouin's result immediately, if the energy and momenta of the material particles are ignored, and the equations are solved. If, on the other hand, the energy and momenta of the sound quanta are ignored, and the equations are solved, the classical Doppler broadening results. These are, however, two extreme cases, and in general both types of phenomena may be expected to be present and to influence each other.

It must here suffice to remark very briefly that the considerations set out above enable us readily to offer a satisfactory interpretation of the experimental results recently reported by Gross[2] on the modification of the fine structure of spectral lines produced by scattering in liquids and solids.

C. V. RAMAN.

210 Bowbazar Street,
Calcutta, Sept. 5.

Activated Adsorption of Hydrogen by Zinc and Chromium Oxides.

THE adsorption of hydrogen by zinc oxide has been the subject of investigation[1] by one of my students, Mr. D. V. Sickman, on a so much more comprehensive scale than that recently recorded by Garner and Kingman[2] that it seems desirable to state the results in outline prior to their publication some months hence.

A slow adsorption of hydrogen on zinc oxide (from the oxalate by ignition at 400° C.) occurs from 0° C. upwards. On 20 grams of material at *circa* 400 mm. pressure adsorption reached 2·9 c.c. in 1345 minutes at 0° C.; at 110° C. the velocity of adsorption increased so that 7·25 c.c. were adsorbed in 1200 minutes; at 184° C. this same amount was adsorbed in 45 minutes and as much as 14 c.c. were adsorbed in the longer time interval. The adsorption is reversible, *all* the hydrogen being recoverable by evacuation at 450° C. The activation energy of the adsorption amounts to 14 kgm. cal. for the main surface covered, with smaller values on the more active areas. By a new mathematical analysis of the velocity measurements Sickman has deduced[1] a heat of adsorption of 21 kgm. cal. per mol, a more trustworthy figure than a value of 16 kgm. cal. deduced from isotherms at high temperatures on a partially deactivated surface. The higher value is in excellent agreement with the value recorded by Garner and Kingman for the heat of adsorption of hydrogen on their $ZnO - Cr_2O_3$ catalyst. This would indicate, as they conclude with respect to carbon monoxide, that the hydrogen is adsorbed on the zinc oxide of the mixed material.

Below 0° C. another type of adsorption occurs which attains equilibrium practically instantaneously with no activation energy. The heat of this adsorption is only 1100 calories per mol. As much as 21 c.c. at −190° C. and 3 c.c. at −78° C. are adsorbed on 20 grams of oxide at 400 mm. From the data cited it can readily be calculated that this type of adsorption is negligible at 0° C.

We are inclined to ascribe the minute adsorption of hydrogen found by Garner and Kingman on the single oxides of zinc and of chromium to the slowness with which activated adsorption occurs at ordinary temperatures on the single oxides in comparison with the rate of adsorption on the mixture.[3] That hydrogen is markedly adsorbed in an activated form by chromium oxide is evident from work by Sherman and the writer in which precipitated chromium oxide (ex nitrate) has been shown to be effective in producing the change from para to ortho-hydrogen at ordinary temperatures. This, as we have already shown,[4] is intimately associated with activated adsorption of hydrogen at such surfaces.

HUGH S. TAYLOR.

Origin of Chromosome Linkage in *Œnothera.*

SEVERAL years ago the hypothesis was put forward that in *Œnothera* new species have arisen through crossing and been perpetuated by the chromosome linkage which, it was assumed, had arisen as a result of crossing between unrelated species (Gates, 1928).[1] It has recently been possible to test this hypothesis experimentally, with results which show that chromosome linkage (catenation)[2] can arise when species or mutants showing no catenation are crossed together.

It is known from previous work that *Œ. deserens* and *Œ. blandina,* both of which are secondary mutant derivatives from *Œ. Lamarckiana,* have seven free pairs of chromosomes in meiosis, and that the same condition exists in *Œ. purpurata,* a species described from Germany by Klebahn.[3] Reciprocal crosses were made between these three forms, which thus furnish us with a triangle of species in which the bivalent chromosomes were all unlinked in meiosis.

A preliminary examination of some of the F_1 hybrids shows the following catenations: *deserens* × *blandina,* ring of 6 and 4 pairs; *deserens* × *purpurata,* ring of 4 and 5 pairs; *blandina* × *purpurata,* ring of 4 and 5 pairs. In all three crosses catenation has thus arisen through hybridisation between forms having only paired chromosomes.

The view is thus experimentally confirmed that the species of *Œnothera,* most of which show catenation, have arisen through crossing between previous species and breed true because of the genetic linkage resulting from that catenation. That heterozygous species can breed true because of apogamous reproduction is a familiar conception. That they can breed true because of catenation (linkage) of the chromosomes in meiosis is not generally recognised, but is now well known in *Œnothera.*

Without going into details, it seems clear that the chromosome-complexes of *deserens* and *blandina* have become different by two chromosome segmental interchanges, involving three non-homologous chromosomes. The results of crossing these forms with *Œ. purpurata* may be explained on the assumption that *purpurata* differs from *blandina* by one of these segmental exchanges and from *deserens* by the other.

A full account of this work and its bearing on problems of chromosome linkage will be published later.

Magnetic Resolution and Nuclear Moment of Rhenium.

FOR some time the spectrum of rhenium has been the subject of investigation in the Amsterdam Laboratory "Physica". With the Hilger E_1 quartz spectrograph we have studied the spectrum of the arc and of the underwater spark. The hyperfine structure and the magnetic resolution have been investigated with the 20-ft. grating in an Eagle mounting.

The following strong complex arc lines: λλ3465; 3460; 3452; 3424; 3399 A., which give absorption in the underwater spark and therefore should be considered as combinations with the ground-level ($d^5 s^2\, {}^6S_{5/2}$), are of special interest. Meggers[1] has identified the first three lines as the combinations ${}^6S_{5/2} - {}^6P_{5/2\ 7/2\ 3/2}$.

From the number of satellites and from the interval rule we conclude that the hyperfine structure originates from the $d^5 s p\, {}^6P$-term, and that the nuclear moment of rhenium is $\frac{5}{2}$, as was suspected by Gremmer and Ritschl.[2]

The hyperfine structure in the Zeeman components of the line λ3460 ${}^6S_{5/2} - {}^6P_{7/2}$ has been resolved. The strongest σ component is split up into six nearly equidistant hyperfine structure components, which indicate also that the nuclear moment is $\frac{5}{2}$. The mean distance of these components is 0·334 cm.$^{-1}$ and gives an interval constant a of 0·095 cm.$^{-1}$ in accordance with the value 0·096 cm.$^{-1}$ obtained from the hyperfine structure without magnetic field. On these six components are partly superposed more feeble groups of non-resolved σ-components.

It seems that the ${}^6P$-term has a slightly anomalous g-value, 1·76 (normal value, 1·714). The observed values for the six subcomponents of the strongest σ-components and the values calculated with $g = 1·76$ and the interval constant of the hyperfine structure without magnetic field are given below. Magnetic field: 38,900 gauss.

Infra-Red Absorption Spectrum of Carbonyl Sulphide.

RECENT developments in the theory of band spectra in the infra-red[1] lend particular interest to all new experimental results for triatomic molecules. We have recently examined the absorption spectrum of carbonyl sulphide, making use of a monochromator method in order to avoid the photochemical decomposition to be expected on exposure of this substance to the full energy of a Nernst filament. We find a complicated spectrum—a fact which in itself demonstrates the lack of symmetry in the molecule: the results are summarised in Fig. 1. In the few cases in which the bands have been resolved, the separation between the P and R branches is given.

In assigning observed bands to certain fundamental frequencies with their corresponding overtones and combinations, due consideration has to be paid to their relative intensities, which are dependent upon the magnitude and orientation of the effective electric doublets concerned. The latter will be governed by the configuration of the molecule; when this is known, the deduced moments of inertia, the interatomic angles and separations must agree with those obtained by other physical methods, such as X-ray analysis or electron diffraction. Finally, the molecular structure must tally with known chemical and thermochemical data.

We have explored at some length the mechanical possibilities of a system of three different masses having various force constants with (*a*) covalent and (*b*) ionic linkings; the tedious calculations involved have at least enabled us to discard certain forms, but we believe we are justified in directing attention to this particular piece of work, inasmuch as it illustrates the need for cautious statements on such matters.

In spite of the experimental detail available, we find ourselves unable to pronounce definitely for either a rectilinear or a triangular structure: if the latter, our results and deductions are more consistent within themselves, but they seem to require two modifications of the substance; if the former, agreement is obtained with Vegard's recent X-ray analysis at the temperature of liquid air,[2] which demands a straight line molecule. Furthermore, thermochemical data indicate that the types of binding in carbon dioxide and carbon disulphide are probably those which exist in carbonyl sulphide.

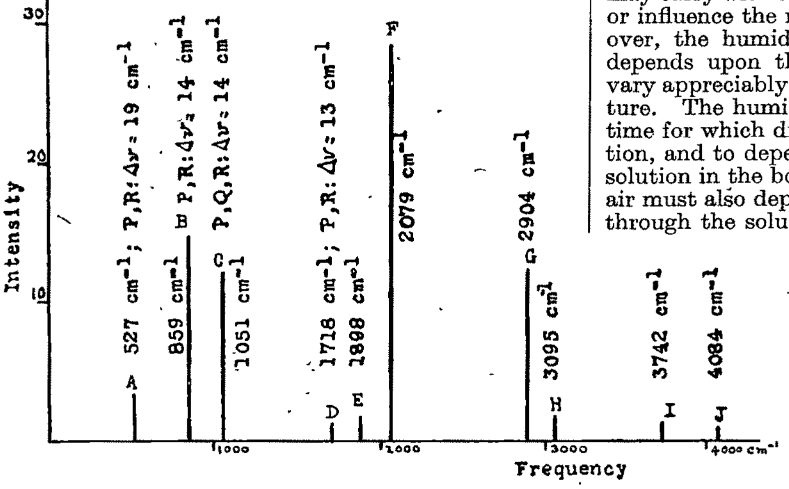

FIG 1.—The near infra-red absorption spectrum of carbonyl sulphide.

It is unfortunate that no determination of the Raman spectrum has been attempted; this is probably a consequence of the ready photochemical decomposition, but perhaps something might be done by examining the light scattered from the crystals at low temperatures.

A Method of Obtaining Air Currents of Different Humidities.

FOR various experiments in which the change of a physical property with the humidity of the surrounding air has to be studied, for example, the calibration of a hair hygrometer, it is necessary to have some means of producing currents of air of different relative humidities. The usual method of attaining this in practice is to bubble air through wash bottles containing solutions of water and sulphuric acid of suitable strengths. A certain percentage of the acid in the solution gives rise to a certain definite humidity to the air in contact with it, and the bubbles of air through the solution are supposed to acquire this humidity.[1]

For some time past experiments have been in progress in this laboratory to investigate the changes in the electrical resistance of pencil lines due to varying humidities of the air to which they are exposed, with the view, ultimately, of evolving an electric hygrometer.[2] In these experiments air currents of different humidities were obtained in the above-mentioned manner. It was found, however, that changes in the resistance when exposed to varying humidities, though regular enough to encourage further experimentation for hygrometric purposes, were not as regular and reliable as one could wish. While investigating causes for such irregularities, they were traced, among other things, to the currents of moist air having been produced by bubbling it through sulphuric acid water mixtures.

It is not unlikely that the current of air so produced may carry with it traces of the acid, which may act on or influence the material under investigation. Moreover, the humidity imparted by a certain solution depends upon the temperature, and therefore may vary appreciably if there are large changes of temperature. The humidity also seemed to change with the time for which dry air was bubbled through the solution, and to depend on the 'empty' space above the solution in the bottle. The humidity of the outgoing air must also depend on the rate at which it is passed through the solution, and so may not always be the same as that which the strength of the solution indicates. Then, again, fresh solutions must be made for each experiment, and even then its strength may alter appreciably towards the end of an experiment if the bubbling has been continued long enough.

In order to get over these difficulties, a method has been devised of obtaining air currents of any required humidities without the above drawbacks. The principle is to mix a current of dry air, dried by any of the usual means, with a current of air saturated with moisture obtained by bubbling air through a bottle full of water. By regulating the strengths of the two currents, any desired humidity can be produced. The strength is regulated by turning a stop-cock or a pinchcock suitably placed in each of the two branches. Each of the two streams is then made to pass through a small, equal length of a capillary tube, whence it passes into a wider tube where the two mix before passing over the resistance. The two branches are also connected to two U-shaped oil manometers, the other ends of the manometers being connected together and to the wide 'mixing' tube.

From calibration curves giving the relationship between the pressure difference as indicated by the manometer when one of the branches is gradually opened, the other remaining closed, and the rate of flow of air as obtained from the volume, collected during a certain time, of water escaping from the aspirator or any other arrangement used to draw air through the apparatus, the humidity of the air in the mixer when both branches are working at any given rate of flow can be calculated. Production of different humidities is obtained by the regulation of the two cocks until, for the rate of flow in progress, the two manometers indicate the requisite pressure differences. An example will make this clear. Suppose the rate of flow is 60 c.c./min. and a 40 per cent relative humidity is sought. Evidently this can be brought about if the rate of flow of the saturated stream is 24 c.c./min. while that of the dry current is 36. Now from our calibration curves we find that a pressure difference of 5·75 cm. of the oil used corresponds with the rate of flow of 24 c.c./min. in the humid air branch and a pressure difference of 8·10 cm. with 36 c.c./min. in the other, dry air, branch. All that would be necessary then to get a 40 per cent humidity in the above case would be to regulate the two cocks so that the two manometers indicate the above-mentioned pressure differences respectively.

None of the disadvantages of the old method affects the new one, which also does away with the large number of wash bottles and attendant laborious manipulations which are needed in the old method, and which constitute yet another drawback to be added to the list given above. Credit for this new device and working out various details in connexion therewith is due to one of my students, Mr. Abdul Basir Pal.

It seems worth while to mention, before concluding, that by working with moist air obtained in this new way and at the same time arranging that the flow of air over the resistance took place at a constant rate, the changes in the resistance due to varying humidities were found by Mr. Pal to be much more regular, reliable, and repeatable than in previous experiments, and thus more helpful and encouraging towards the devising of our electric hygrometer. Full details will be published elsewhere.

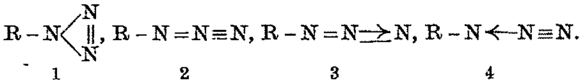
Structure of the Azides, from their Electric Dipole Moments.

As is well known, the chemical evidence regarding the structure of the azides is far from being unambiguous, and four formulæ have been proposed,[1, 2, 3]



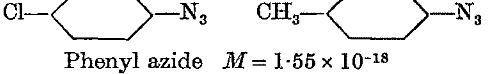
$$R-N\langle{}^{N}_{N}\| ,\quad R-N=N\equiv N,\quad R-N=N\rightarrow N,\quad R-N\leftarrow N\equiv N.$$

1 2 3 4

Of these, 2 is ruled out because the central nitrogen atom would have a shared decet of valency electrons, which, for an element in the first short period, is impossible.

Lindemann and Thiele concluded from parachor measurements that the ring structure was the correct one, and it seemed to be of interest to apply other physical measurements to the solution of the problem. Accordingly, the electric dipole moments of phenyl azide, *p*-chlorphenyl azide, and *p*-tolyl azide have been determined and found to be 1·55, 0·35, and $1{\cdot}96 \times 10^{-18}$ e.s.u., respectively.

From the comparative smallness of the moment of phenyl azide, formula 3 can be ruled out, as in this the moments due to the C–N link and the N→N link would be at an angle of less than 90° to one another and would probably give a resultant moment of $3-4 \times 10^{-18}$ e.s.u. (compare nitrobenzene $M = 3{\cdot}9$ and di-phenyl-sulphoxide $M = 4{\cdot}1 \times 10^{-18}$ e.s.u.). It is possible to discriminate between the two remaining formulæ, because in 1 the negative pole of the group dipole would be farther from the benzene ring than the positive one,[4] while in 4 the reverse would be the case because of the direction of the co-ordinate link. From the moments of *p*-chlorphenyl azide and *p*-tolyl azide it is clear that actually the negative pole is farther from the benzene ring:[5]



Phenyl azide $M = 1{\cdot}55 \times 10^{-18}$
Chlorbenzene $M = 1{\cdot}56 \times 10^{-18}$
Toluene $M = 0{\cdot}45 \times 10^{-18}$

and therefore the ring structure is the most probable of the three. There is, however, a still stronger argument in its favour.

It will be noticed that the moments of *p*-chlorphenyl azide and *p*-tolyl azide are almost exactly equal to the difference and to the sum, respectively, of the single group moments (the moment $0{\cdot}35 \times 10^{-18}$ of the *p*-chlor derivative corresponds to a polarisation of only 2·5 c.c. and by the method of measurement used it is impossible to distinguish this from zero, owing to the possible atom polarisation).[6] This indicates that the moment of the azide group lies almost exactly along the direction of the valency linking it to the benzene ring. Now, neither formula 3 nor formula 4 could lead to this, since the main moment would be in that part of the group which is inclined at an angle, not equal to 180°, to the C–N link. In the ring formula, however, the moment of the N=N link would be zero, and that of each N–N link, though the nitrogen atoms are not in exactly the same state of combination, would be almost zero. Therefore the only appreciable moment would be that of the C–N link itself, and this would explain the fact observed.

It is therefore fair to say that the evidence of the dipole moments is strongly in favour of the original ring structure.

Raman Spectra of Liquid Mixtures.

IT is well known that mixtures of polar liquids often exhibit marked deviations from the additive law in respect of such properties as density, vapour pressure, viscosity, and refractive index. Such changes taking place in aqueous solutions are usually attributed to the formation of definite hydrates. Important evidence concerning the constitution of liquid mixtures is furnished by a study of their Raman spectra. I have made a careful examination of the spectra of aqueous solutions of methyl alcohol, acetic acid, and pyridine over a series of concentrations, and have shown that marked variations occur in the spectra. The phenomena noticed include cases in which some Raman lines of the solute suffer displacements, or broaden or split up into components, or undergo changes in relative intensity.

It must suffice here to mention only the effects observed in acetic acid–water mixtures. These refer principally to the behaviour of the broad line of wave-number displacement 1667 found in the spectrum of pure acetic acid and usually attributed to the C=O bond in the molecule. Slight dilution of the acid to 95 per cent strength introduces a new faint component to this line at 1712 cm.$^{-1}$. The latter is observed to increase in intensity relatively to the first on further dilution to 90 per cent and 85 per cent concentrations. Finally, at 75 per cent, which corresponds nearly to the composition $CH_3 . COOH, H_2O$, only one broad line at 1712 cm.$^{-1}$ is present. Further dilution produced no change, except for a slight sharpening of the 1712 line.

From these observations, it would appear that a hydrate is formed of the composition mentioned. It may be remarked that the acetic acid solutions exhibit a point of maximum density at about the same concentration (77 per cent) at 25° C.

Research Items.

An Archaic Egyptian Figurine.—M. G. Loukianoff describes and figures in *Ancient Egypt* for June 1930 a rare type of small figurine of ivory, purchased in Cairo in 1927. The figure is one and a half inches high, almost entirely black and remarkably heavy for its size, weighing 12·6 grains. It represents a seated infant with legs doubled back, and, as may be inferred from the inclination of the right arm, which is broken, and a mark on the lips, sucking its finger. The lips are a little twisted, as owing to the position of the finger in front of the mouth, the artist was unable to fashion them with an unbroken stroke. The left hand lies extended along the knee. The head is crowned by a little cap fitting close to the cranium. From the artistic point of view the minute accuracy of the work is to be remarked; while equally characteristic is the cast of the features, which is not Egyptian, the nose being large and the cheek-bones prominent. The attitude of the figure is that which was traditional for the infant Horus from the early dynasties to the decline of Egyptian civilisation. It is the same as that of the lapis lazuli figurines recently found in the tomb of Tutankamen, in which the Pharaoh is represented as the infant Horus. The motive of the present example is so exactly repeated in the alabaster figurine of Pepy II., found last year at Saqqara, that it would suggest an identity of date, if it were not that there is a still closer resemblance to the ivory statuettes of pre-dynastic date discovered by Petrie at Abydos and Ballas. The type is, indeed, very different from that of the early dynasties—a fact which immediately suggested its attribution to the archaic epoch of Egyptian art. It has been examined by Dr. Reisner, who pronounces it authentic and assigns it to Dynasties 0-2.

A Sea-lion Census.—In 1930 a census of the sea-lions off the coast of California was made, in view of the possibility that recommendations to the legislature might be desirable. It was made at the height of the breeding season, from mid-June to mid-July, and although no census was made in 1929, the figures made an interesting comparison with the censuses of the two previous years (Paul Bonnet, *California Fish and Game*, vol. 17, p. 150; 1931). Of Steller's sea-lion, with twelve rookeries the largest containing 2500 individuals, the grand total in 1930 was 6360, against 4593 in 1928 and 5781 in 1927. The California sea-lion, with eleven rookeries of which the largest had 340 individuals, numbered 968 in 1930, 1338 in 1928, and 892 in 1927. The presence of more Stellers in 1930 than in 1928 is attributed to migrations from the north, where the animals are still hunted under a bounty system; while the decreasing population of the California sea-lion is due to the unrestricted collecting and hunting of the previous two years. The casual shooting by fishermen of sea-lions in the neighbourhood of fishing operations does not seem to lower the population to any great extent, but the slaughter due to professional trimming hunters and to collectors who capture living specimens for zoos and circuses is a serious menace, and has brought about the material reduction and even the abandonment of several of the larger rookeries.

***Blepharoceridæ* of Japan.**—This small family of dipterous insects has a very wide distribution, and is remarkable on account of the peculiar morphological characters exhibited in the different post-embryonic stages. The larvæ and pupæ are particularly interesting in that they are aquatic and confined to rapid mountain streams. Until recently, only four species of the family were known from Japan, but neither their larvæ nor pupæ had been discovered. In *Memoirs of the College of Science*, Kyoto Imperial University (Series B, vol. 6, 1931), Mr. Sirô Kitakami describes the results of his researches on this family. His discoveries have led to the recognition of five genera and eighteen species in Japan. Of these, one genus, *Parablepharocera*, and fourteen species are described as being new, the largest number of species belonging to the genus *Philorus*. In the new genus *Parablepharocera*, the adult is distinguished from *Blepharocera* by the much longer vein Rs, and its larva bears a pair of finger-like processes on each side of the first six abdominal segments, together with a pair of caudal appendages. In *Blepharocera*, it may be added, neither type of organ is evident. In the pupal stage the two genera are scarcely separable from each other. The paper is well illustrated with ten plates of carefully drawn figures portraying structural characters of the different stages of the species described.

Chromosome Homologies in Wheat, Rye, and Aegilops.—In a paper on chromosome homologies in wheat, rye, and *Aegilops*, Prof. W. P. Thompson (*Canadian Jour. Research*, vol. 4, p. 624) summarises in a series of tables the results of crosses among members of these three related genera, as regards chromosome pairing in the hybrids. A number of workers have drawn various conclusions regarding the relationships of species from the way in which the chromosomes pair in their F_1 hybrids. In this way it has been concluded that the einkorn (diploid) wheats have an A set of seven chromosomes, the emmer (tetraploid) $A+B$ and the vulgares $A+B+C$; similarly that *Aegilops cylindrica* has $C+D$ sets and *A. ovata* $D+E$ sets. There are, however, difficulties and inconsistencies in the application of these conceptions of chromosome homology, for the cytological results (pairing) do not always agree with the genetical ones. Thus, rye chromosomes are D as judged by their mating in hybrids with *A. triuncialis*, but the genetic characters are not those associated with D. Again, the morphological differences found within the chromosomes do not correspond with their mating peculiarities. Thus, several of the chromosome types in *T. dicoccum* and *T. polonicum* are not found in *T. vulgare*, although every chromosome in these two species finds a mate in crosses with *vulgare*. It is believed that with further work these anomalies will be cleared up, and that the cytological behaviour will throw further light on evolutionary divergence in these forms.

Gyromagnetic Effect for Salts of the Iron Group.—The small spin which a body acquires when it is magnetised is connected closely with the behaviour of the electrons in the atoms in the magnetic field, and it is theoretically possible to decide in certain cases between theories of the action of the field from the *gyromagnetic* effect. This has been done for certain ions of chromium, cobalt, and iron by W. Sucksmith, in an investigation of extreme delicacy which is described in the issue of the *Proceedings of the Royal Society* for September. The salts used have an even smaller susceptibility than dysprosium oxide, the only non-ferromagnetic body which had been studied hitherto, and the angular momenta generated were correspondingly more difficult to measure. The method employed was again that in which a resonant angular movement was set up in an alternating field. The results show that of the various theories which have been advanced, that which supposes the angular momenta of the effective electrons due to their intrinsic spins and their orbital motions to be separately quantised relative to the field axis is the most nearly correct, and further, that the orbital moments may be wholly or partially suppressed by the fields of neighbouring ions. Measurements were also made upon manganese ions, but in this case the conflicting theories all predicted the same result, which was actually obtained.

Reflection of X-Rays.—Some results of much interest in connexion with long X-rays are contained in three papers from Prof. T. H. Laby's laboratory, which appear in the September number of the *Proceedings of the Royal Society.* The first of these, by R. T. W. Bingham, contains a description of the construction and use of a compact vacuum spectrometer; this is of the Seeman single slit type, and was specially designed to give a high intensity of radiation at the photographic plate, together with accurate angular measurements. In the second paper, Mr. Bingham and Prof. Laby describe some investigations on the reflection and diffraction of soft X-rays. They find that these are reflected from surfaces of glass, quartz, and stainless steel at angles very much greater than the critical angle that would be expected theoretically. This fact increases considerably the range of angles for which gratings can be used with this radiation, and has been employed in some new determinations of relative wavelengths. It also permits of focusing of long radiation by a spherical mirror at large angles of incidence. The last paper, by Mr. Mohr, deals with certain details of the total reflection of long X-rays. Within the limits of experimental error, agreement was found between the observed and calculated values of the critical angle, and for the rate of fall of intensity near the critical angle, for the light substances quartz, calcite, and glass, but not for the denser bodies steel, silver, and gold, it being found that increasingly large discrepancies occur with increasing density of the reflector.

Inertia of Loud-Speaker Vibrating Diaphragm.—In addition to the theoretical difficulties of treating the many variable factors involved in loud-speaker design, there are also numerous experimental difficulties concerned in the laboratory measurement of the quantities. Following a treatment (*Phil. Mag.*, **11**, 1-54) of the theory and performance of certain types of modern acoustic apparatus for reproducing speech and music, Dr. N. W. McLachlan has now given an account (*Phil. Mag.*, **11**, 1137-1152) of five methods, each necessitating the measurement of the inductance of a coil situated in a magnetic field, of measuring the accession to inertia of a vibrating diaphragm driven by the reaction between the magnetic field and that of the alternating current in the coil. Three measurements of the inductance are made respectively with the coil fixed, free to move in air of known density and free to move *in vacuo.* In the free condition the value of the inductance depends on the effective mass of the moving system. When vacuum equipment is not available, the necessary conditions for the third measurement can be simulated by removing the diaphragm from the moving coil. Experimental arrangements and precautions necessary to attain accuracy are discussed in detail, and the importance of ensuring that the diaphragm move as a whole is emphasised. The results obtained for a conical diaphragm are in good agreement with those computed from Rayleigh's formula for a rigid disc. It is shown that with a limited size of baffle the accession to inertia decreases with frequency.

Astronomical Topics.

An Interesting New Minor Planet.—On the average three new minor planets are discovered every week, so such announcements are received with equanimity. But when the new object has an unusual rate of motion the case is a little different, for it implies either proximity to the earth or that the body lies on the outer fringe of the asteroid region. *Circular* No. 465 of the Berlin Rechen-Institut announces that a new planet designated 1931 *RA* was found by Herr Reinmuth at Königstuhl, which had the remarkably slow motion of -20^{sec} per day in R.A., and 1′ south in declination; this is slower than the usual rate of the Trojan planets when near opposition, as the new planet was. The motion was verified by another observation two days later. The slow motion may arise either from great distance or from the linear velocity of the planet being nearly the same as that of the earth. In either case the body is deserving of careful observation, so the positions are given as a guide to observers:

	U T.	R.A.	N. Decl	Mag.
1931 Sept.	7^d 23^h $49·1^m$	23^h $38·9^m$	6° 34′	13·7
	9 21 59·5	23 38·2	6 32	

The second observation was a visual one, made by M. Mündler. The observation of minor planets is one of the principal lines of work at Konigstuhl; the earliest image of Pluto that has yet been identified was found on a plate exposed there on Jan. 23, 1914.

Van Gent's Short Period Variable.—Reference has been made in this column to the variable discovered by Mr. H. van Gent in R.A. 8^h $10·6^m$, S. Decl. 18° 45′, with a period of 100 minutes. It was noted that photographic study of the light changes was difficult, owing to the considerable variation during the time of exposure. Mr. Harold L. Alden contributes a paper on the star to *Astr. Jour.* No. 958: the star can be photographed at maximum with 2 minutes' exposure with the Yale 26-inch refractor at Johannesburg. Fifteen plates were taken on 11 nights, giving 56 exposures of the variable. The light range is from 14·05 to 15·12. The light-curve shows an extremely rapid fall after maximum (about 1 magnitude in 7 minutes). The curve is then nearly horizontal for about 40 minutes; the increase of light is fairly uniform for the remaining 53 minutes. In Cepheid variables the increase of light is usually more rapid than the decrease, so that this star differs notably from them.

A New Cluster of Faint Nebulæ.—Quite a number of clusters of faint spiral nebulæ have been detected in recent years. *Astr. Nach.* No. 5815 contains an account by Dr. W. Baade of a new one that he detected on plates taken with the large reflector at Bergedorf Observatory, Hamburg. Its position for the equinox of 1925·0 is R.A. $10^h 54·7^m$, N. Decl. 57° 11′, about half a degree from the star Beta Ursæ Majoris. It extends over a region some 24′ by 17′; the southern part of the region is filled by a densely packed cluster of very faint nebulæ (probably fainter than mag. 17). They are on the limit of visibility, and no structure can be detected. Dr Baade concludes that the nebulæ are considerably more distant than those of the other cluster, also in Ursa Major, that he announced a few years ago.

International Illumination Congress.*

On Sept. 8 the International Illumination Congress proceeded to Buxton, where, on the evening of arrival, there was a demonstration of railway light signals and railway coach lighting at the Buxton railway station. The following day was occupied by a visit to Sheffield, in the course of which numerous local steel works and other places of interest were seen, and an opportunity was afforded of inspecting the Corporation Public Lighting Department, under the supervision of Mr. J. F. Colquhoun. While most of the factories were of considerable technical interest, members were dismayed at the very unsatisfactory lighting conditions prevailing in some of them.

The following day was devoted to sessions at which series of papers on industrial lighting, architectural lighting, the lighting of railways and mines, farm and horticultural lighting, and light sources were read. In the Industrial Lighting Section, Dr. H. Lux (Germany) presented the recommendations of the German Illuminating Engineering Society on this subject, and Herr N. Goldstein and Herr F. Putnoky discussed the lighting of textile mills. A bulky review of current practice in the lighting of factories by gas was presented by the Society of British Gas Industries. Perhaps the most interesting contribution in this section was that by Dr. M. Luckiesh and Mr. F. K. Moss (United States), who made a plea for 'humanitarian foot-candles', that is, the provision of an intensity of illumination beyond the requirements of safety and in excess of demands from the point of view of production.

The section which aroused most interest was possibly that dealing with architectural lighting, on which seven papers were read. Developments in Great Britain were surveyed by Mr. R. W. Maitland and Mr. W. J. Jones, and decorative lighting in France by MM. H. Maisonneuve and J. Wetzel. A paper on "Illumination and Architecture" by Mr. L. Kaeff (Holland) contained some interesting speculations on the influence of climatic conditions on architectural design, and the effect of varied conditions of natural and artificial lighting on shadows cast by embellishments on buildings. The engineering aspects of architectural lighting were dealt with by Mr. W. J. Jones, and researches of a mathematical character were reported by MM. Dourgnon and P. Waguet. These papers gave rise to an interesting discussion, in the course of which the application of laws relating to the illumination derived from a luminous point, a line, and illuminated surfaces were analysed, and views on the best methods of securing the co-operation of the architectural profession in illuminating engineering considered. Interesting information on procedure in the United States, where courses of instruction for architectural students in illumination and, conversely, lectures on architecture for illuminating engineers have been arranged, was forthcoming.

The other papers covered a wide variety of topics. Mr. A. Cunningham outlined the development of lighting on British railways, and discussed such problems as the lighting of platforms, goods sheds, and goods yards, for which tentative standards were suggested and reference made to the use of floodlighting in connexion with shunting operations. Convenient designs for illuminated station name-plates were illustrated. This paper was supplemented by a similar one by M. J. W. Partridge outlining practice on the French railways: in this, further information on the use of floodlighting for the illumination of large open spaces was furnished. Papers on the lighting of mines deplored the very low standard of illumination prevailing and advocated the use of miners' lamps of higher candle-power. The possibility of floodlighting the coal face, by the aid of electric light, was considered. In this connexion data illustrating the influence of conditions of illumination on safety and output in certain mines in Silesia were presented by Dr. L. Schneider (Germany). Mr. W. A. Villers was responsible for a paper on cinema studio lighting, in which the use of incandescent lamps for 'talking' films was illustrated. There were several papers reviewing processes in incandescent lamp manufacture, and comparative data on the qualities of sunlight and artificial daylight. Finally, there was a group of papers, "Electric Light on the Farm" (R. Borlase Matthews), "Plant Cultivation with Electric Light in Sweden", and the "Artificial Lighting of Greenhouses in Germany", all of which illustrated the important part that light may play in connexion with horticulture.

At Birmingham, where the Congress next proceeded, there were interesting visits to local works. That to the glass works of Chance Bros., Ltd., at Smethwick, was notable for some pleasing demonstrations, such as methods of tracing the rays from optical equipment by means of chemical smoke. The experimental lighting in the Hagley Road, where sections are lighted alternately by gas and electricity, was of considerable interest. The papers read at Birmingham were less varied than at Buxton, being chiefly concerned with signalling apparatus. Four papers, all from Japan, described signal systems in use on the Japanese railways and experiments on the production of coloured glasses. There was a good paper by Mr. J. P. Bowen, engineer-in-chief to Trinity House, reviewing the development of lighthouses. Informative contributions by A. V. Blake and W. M. Hampton and E. Schuppen discussed the development of traffic control signals in Great Britain and Germany respectively. The former paper showed how requirements in Great Britain chiefly demand the independent control type of signal, and discussed such technical problems as the best form of distribution curve and the elimination of 'phantom indications' of signals. Herr E. Schuppen studied the use of simultaneous and progressive systems of control in Berlin, the length of individual cycles, and the design of automatic controllers. It is stated that since automatic control has been introduced, 20 per cent more traffic is carried by the same streets in Berlin, and with very much less hindrance.

In the Section on Motor-Car Headlights there were communications from France and Great Britain reviewing recent progress in methods and design. Dr. F. Born (Germany) discussed in considerable detail the basis of an international agreement on motor-car lighting, assuming the provision of two kinds of light, a main beam and an anti-dazzle beam; 100 m. has been proposed as a minimum value for range of the main beam and 25 m. for the anti-dazzle (alternative) beam. Provisions for limiting glare are most easily based upon the illumination at the observer's eye. Suggestions for standardising the various constituent parts were also made. A report from the Japanese Committee on Motor Vehicle Headlights described experiments with the R.A.C. disc and suggested some modification in the test with this apparatus. Other papers treating light distribution and heterochromatic photometery were of a somewhat specialised character, either dealing with the details of photometric processes or recording experiments determining the order of accuracy attainable in comparing sources of different colour. The final day at Birmingham was devoted to a day-trip to Stratford-on-Avon, after which members proceeded to Cambridge.

---

* Continued from p. 589.

The meeting at Cambridge was generally regarded as one of the most successful parts of the Congress, and was well attended. In the course of the visit, there were trips to Ely and Peterborough (the latter an evening visit so that the artificial lighting of the cathedral might be inspected) and an address on "The Light of the Stars" by Sir Arthur Eddington. There was also a comprehensive demonstration of anti-dazzle devices by the Royal Automobile Club, which was instructive in demonstrating recent progress in this field. A considerable amount of work was done, sessions being devoted to such matters as street lighting, daylight illumination, nomenclature, definitions and symbols, photometric test-plates, traffic signals, glare, motor-car headlights, photometric accuracy, aviation lighting, heterochromatic photometry, the lighting of schools and factories, etc.—on most of which reports reviewing progress and, in some cases, leading to definite recommendations were presented.

Amongst the numerous points on which decisions were taken the following may be noted. It was agreed that in visual photometry the most accurate measurements are possible with illuminations between 5 lux and 20 lux, and that in the laboratory a mean error of an order not exceeding 0·25 per cent is possible, whilst in commercial work a limit of 3 per cent may be attained. In regard to daylight, the 0·2 per cent daylight factor (at present applied in Great Britain legally in connexion with Ancient Lights cases) was regarded as a minimum—which would be definitely inadequate in the case of work involving much visual discrimination. It was further agreed that a committee should be set up to consider the standardisation of artificial daylight. The Section on Lighting Education formulated many recommendations, such as the inclusion of instruction in illumination at post-primary schools and in architectural colleges, and the organisation of at least one full specialised course in illuminating engineering in each country. In connexion with headlights, the distinction between the 'driving beam' and the 'passing beam' was recognised, and steps to limit glare and ensure adequate illumination were proposed. It is interesting to observe a consensus of opinion that coloured beams of light are of no material advantage in fogs.

Other resolutions related to traffic control and street lighting, a desire for fuller data in regard to the influence of traffic signals on road accidents being expressed. In connexion with street lighting, it was recommended that, in order to facilitate international comparisons, contributors should give (*a*) a description of the fitting, (*b*) particulars of spacing, and (*c*) both average and minimum illumination.

An invitation for the next meeting of the International Illumination Congress to take place in Germany was accepted for 1934, when the president will be Dr. A. R. Meyer.

International Congress for the Testing of Materials.

THE New International Association for Testing Materials held its first congress at Zurich on Sept. 6–11. Although this was the first congress of the New International Association, eleven international congresses on the testing of materials have been held in the past. Ten of these were held by the original International Association which was formed more than thirty years ago under the auspices of Tetmayer and Bauschinger. This Association was broken up during the War, but a new International Association was formed at a congress in Amsterdam which had been arranged in September 1927 by the Dutch Association for Testing Materials. The new Association, although it is continuing the most valuable work of its predecessor, differs from it in many important respects, particularly by being a much simpler organisation, which avoids so far as possible the formation of numerous permanent committees, and also by entirely eliminating all questions of international standard specifications.

The Congress at Zurich was presided over by Prof. A. Mesnager, of the Conservatoire National des Arts et Métiers, Paris, and its work was carried out in four sections, namely: (*A*) Metals, under the presidency of Dr. W. Rosenhain, London; (*B*) Inorganic Materials, stone, cement, concrete, etc., under the presidency of Prof. M. Roš, director of the Swiss Federal Testing Laboratory at Zurich; (*C*) Organic Materials, bitumen, paints, rubber, etc., under the presidency of Prof. Roos af Hjelmsater, Stockholm; (*D*) Questions of General Importance, under the presidency of Prof. Goerens, of Messrs. Krupp. Most of these sections held five sessions, each occupying a whole morning or afternoon and each devoted to the discussion of a single selected subject, upon which a number of reports by experts of international standing were first presented in brief abstract, a general discussion following. The reports were of a very high order of interest and importance, and particularly good discussions took place. The work of the Congress was, throughout, animated by the spirit of international co-operation and friendship, and by the desire of all those taking part to further the common cause of improving our methods of testing and of advancing our knowledge of the properties of materials, upon which satisfactory methods of testing must be founded.

In Section *A*, the subjects discussed were cast iron, notched-bar impact testing, fatigue, materials at high temperatures, and the progress of metallography. In regard to cast iron, considerable divergence of opinion and practice appears to exist, particularly between the French engineers and those of other countries. As a result of the discussion, however, the president of the Section hopes to issue a brief summary acceptable to all those who took part. Such a summary should serve as a guide to those bodies whose business it is to deal with standardisation, both national and international. The same applies to the notched-bar impact test, where the adoption of a standard test piece affording comparable results in different countries is particularly desirable.

In Section *B*, the importance of geological factors in the testing of stone was discussed, and new data on the resistance of road-building materials to shock were presented. Cement testing, concrete testing, and the testing of reinforced concrete were also discussed at length, the latter subject presenting a series of particularly important problems.

Section *C* dealt with the problems of asphalt or bitumen, which has attained so much importance in regard to road construction, and special attention was devoted to the question of nomenclature, upon which international agreement appears to be highly necessary. In regard to the testing of timber, the decisive importance of moisture content on all strength properties was emphasised; it is suggested that consideration of this factor clears up the existing difficulties in the relations between compression, bending, and tensile strength. Questions of ageing of materials such as oils, textiles, synthetic resins, and rubber were also discussed, the importance of temperature, oxygen, and light being considered. A discussion on viscosity brought out a consensus of opinion that the 'poise' should be adopted as the unit of dynamic viscosity and the 'stokes' as the unit of kinematic viscosity. Tables for the conversion of data expressed in other units to this system are to be prepared. Considerable attention was also paid to the question of solid fuels, particularly with regard to the sampling of coal.

In Section *D*, the subjects treated related to the determination of grain size in powdery materials, the calibration of testing machines, and the general conceptions implied by the terms 'elasticity', 'plasticity', 'toughness', and 'brittleness'. A general discussion on the latter question proved of particular interest.

At the opening meeting of the Congress, the delegates of some thirty-four nations made brief speeches in reply to the opening addresses of the president and the representatives of the Swiss Federal Government and of the Canton and City of Zurich; they paid tribute to the early work of Tetmayer at Zurich and to that of his present successor, Prof. Roš, for the great work he had done in the successful organisation of the Congress in his capacity of general secretary of the International Association. Great Britain was represented by Sir Henry Fowler and Dr. W. Rosenhain. The latter, as representative of Great Britain on the Permanent Committee of the International Association, was the bearer of an invitation from the British Committee to the International Association to hold its next Congress in London in 1935. At the final plenary session of the Congress, this invitation was accepted, and Dr. Rosenhain was elected as the next president of the New International Association. It is hoped that the sectional presidencies will be filled as follows: (*B*) Dr. Barta, Czechoslovakia; (*C*) Prof. Suenson, Denmark; (*D*) Dr. G. K. Burgess, director of the Bureau of Standards, U.S.A. The presidency of Section *A* has not yet been filled, but it is hoped that it may be accepted by Prof. Goerens, of Essen.

It is interesting to note that on this occasion, although British participation was not very numerous—some five hundred members attended the Congress, and of these not more than twenty were British—yet the British representatives took a very active and important part in the work of the Congress, and the importance of their work and influence was fully appreciated and is likely to prove of value to British technical and industrial prestige throughout the world.

Association of Special Libraries and Information Bureaux.

THE eighth annual Conference of the Association of Special Libraries and Information Bureaux was held at Lady Margaret Hall, Oxford, on Sept. 18–21, and the attendance and papers presented at the Conference, as well as the discussions, manifested a growing appreciation of the value of such a clearing house for multiplying sources of specialised information both in science and industry. Anxiety regarding the future of the Association in view of its unsatisfactory financial situation, which Dr. R. S. Hutton emphasised at the annual general meeting, appeared indeed rather to intensify the sense of the value of the Association's work, and several speakers at this and other sessions urged the importance of defining more clearly the functions of A.S.L.I.B. so as to prevent undue diffusion of effort.

The need for some such central index and pointer to sources of special information was repeatedly emphasised, and discussions on the Library and Information Departments of the Royal Institute of International Affairs and on the League of Nations and the International Labour Office as sources of information for economic affairs ultimately issued in a resolution urging the Council to promote the effective organisation of some such central index or means of co-ordination. An offer to provide clerical assistance in such a move was made by Mr. B. M. Headicar, of the London School of Economics, and the experience of the groups established during the year in Yorkshire and in Lancashire and Cheshire has indicated the value of local co-operation and contact, as well as central organisation in promoting the rapid exchange of information between members to their mutual advantage.

Special interest was supplied to the opening session of the Conference by a paper in which Prof. A. M. Carr-Saunders analysed some of the problems of professionalism, including professional training and the restriction of entry to professions to which allusion has recently been made in NATURE. State control or interference in professional matters is largely determined by the necessity of maintaining a reasonable standard of competence as in law and medicine, or of securing the public safety as in regulations relating to marine officers. When the contact between the members of a profession and the public is only indirect, as in certain professions the legal restriction of which has been attempted in recent years, it is much more difficult to establish a case for State regulation. The growth of specialisation makes the question of competence much more difficult, and even in the medical profession the question of dealing with or proving incompetence has not been entirely solved.

Prof. Carr-Saunders, pointing out the dangers inherent in registration and professionalism, suggested that as an alternative to multiplication of self-governing professional organisations a wider use might be made of powers obtained under and administered through the Privy Council as a means of maintaining high professional standards. Referring to professional training, Prof. Carr-Saunders stated that in the modern tendency for professional training to be given at the universities, the universities are reverting to their original functions. The development of the Association of Special Libraries and Information Bureaux is an indication of the importance of these questions in regard to librarians and the competent handling of information.

In the session over which Sir Charles Sherrington presided, Mr. E. N. Simon directed attention to the valuable and original scientific information which is now contained in the publications of industrial firms and frequently only available in such literature. In recent years the character of such publications has totally changed, and technical service literature now contains an increasing amount of information and data of direct practical, scientific, and technical value to scientific workers in general and not to research workers in industry alone. Other speakers who confirmed this view directed attention to the difficulty even in industry of rendering such information readily accessible, and the importance of co-operation in making it known, whether through the offices of A.S.L.I.B. or otherwise, was evident.

Sir Frederic Nathan's paper on international abstracting and indexing of scientific and technical literature was a further presentation of the scheme he outlined last year before the Chemical Engineering

Group of the Society of Chemical Industry, which has since been discussed at a special conference on abstracting convened by Mr. H. T. Tizard at the Imperial College of Science and Technology in July, as well as at the recent conference of the International Institut de Bibliographie at the Hague, at which Sir Frederic presented a similar paper. The scheme met with severe criticism on several points, particularly from representatives of industry, and it is evident that the adoption of the Universal Decimal Classification as a basis meets with serious difficulties in the more highly specialised field of industry. Whether the advantages of a universal classification designed to facilitate the correlation of all branches of knowledge outweigh such difficulties in particular and detailed applications is probably a matter for the industries concerned to determine. A system admittedly must represent a compromise. A weakness inherent in Sir Frederic Nathan's scheme is the well-known disparity in the character of the abstracts prepared by different countries, and some limitation of the principle that each country should be responsible for preparing its own abstracts is inevitable, even if only in grouping of the smaller countries. There must be general confidence in the abstracting efficiency of all participating countries if the scheme is to be acceptable generally. Furthermore, translation provides an acute practical difficulty whether the translations are provided by the abstracting country or made in other countries from the abstracts provided. It was further pointed out that it is important that the length and detail of the abstract should bear some relation to the geographical or lingual accessibility of the paper abstracted. Here again we are faced with a question of comparison and of evaluating obvious advantages against serious disadvantages which in practice may or may not outweigh the advantages.

Other papers presented at the Conference included one by Dr. A. Preeder, Director of the Library of the Technische Hochschule, Berlin, describing an ever-ready printed catalogue, and a discussion of the value of films as a medium of information in education, science, and industry by Mr. F. A. Hoare. At the concluding session of the Conference, Dr. E. Shenkman gave an account of the Russian Five-Year Plan in its special relation to British industry and commerce. An exhibition of sound films was given during the Conference by the Western Electric Co.

Birthdays and Research Centres.

Oct. 11, 1864.—Sir **Henry Lyons**, F.R.S., Director of the Science Museum, South Kensington, and formerly Director-General of the Survey of Egypt.

Although only a part of the new Science Museum as planned by the Committee of 1911 has yet been completed, the reorganisation and development of the collections have already occupied several years. They are now being increasingly used by technical visitors and students, as well as by the general public, in large numbers, and they are supplemented at frequent intervals by special exhibitions to illustrate recent developments in various groups.

As soon as the next block of the Museum has been constructed, the representation of current practice in all branches, which is most urgently needed, can be more adequately provided for than is now possible.

Oct. 11, 1875.—Sir **Arthur W. Hill**, K.C.M.G., F.R.S., director of the Royal Botanic Gardens, Kew.

The direction of the affairs of the Royal Botanic Gardens, Kew, covers so wide a range both in the realms of systematic and applied botany and also in the domain of practical horticulture that the Director is unfortunately left with very little spare time for carrying out botanical investigations himself. He is, however, able to suggest to the members of his scientific staff and visiting botanists various problems which come to his notice on which investigation is needed, and for the solution of which Kew affords such unrivalled opportunities. These relate principally to matters of systematic or economic interest which affect botanical or agricultural progress in the Empire.

My own long connexion with Kew gives me the opportunity of noticing many points of great scientific interest urgently in need of investigation, which I seldom have time to study in detail, nor is there any member of the Kew staff who can be diverted from his proper sphere to carry out the necessary research.

Kew is very much in need of the assistance of one or two research students to work in the laboratory, herbarium, and gardens on these many interesting problems: it may be in plant physiology, ecology, or general morphology; and if such posts could be suitably endowed for university graduates, there would be ample opportunity for the research students to work at these problems, since all facilities in the way of living material, laboratory accommodation, our library and herbarium collections, as well as personal direction, are available at Kew.

As an example of what has been done in the past at Kew may be cited the work of Brown and Escombe, Dr. D. H. Scott, and other voluntary research workers.

Oct. 11, 1881.—Dr. **L. F. Richardson**, F.R.S., Principal of Paisley Technical College and School of Art.

The mystery of the connexion between mind and matter may be approached by considering time and intensity. For time and intensity belong both to physics and to psychology, as Fechner emphasised. I have found that the variations in time of mental images can be estimated quantitatively, and that equations describing the time-changes can be fitted to the observations (*Jour. General. Psych.*, April–July 1929).

Another clue to the same problem is suggested by the behaviour of the neon lamp, which in some of its time-relations resembles human behaviour; for example, B. van der Pol's model of the heart (*Phil. Mag.* Suppl., Nov. 1928). Also, I have arranged three neon lamps so that the lighting of any one of them will extinguish any other, just as rival thoughts extinguish each other (W. McDougall's "inhibition by drainage"). Many other analogies between mental images and sparks are collected by me in the *Psychological Review* (May and July), 1930.

Another, and more natural, clue is provided by periodic electrolytic phenomena (E. S. Hedges, Nature, **128**, 398, Sept. 5, 1931).

Oct. 11, 1886.—Mr. **A. C. G. Egerton**, F.R.S., reader in thermodynamics in the University of Oxford.

My immediate interests lie in three directions: (1) researches at high temperatures, 3500° and above; (2) study of processes of combustion; and (3) properties of vapours. The first entails a study of gaseous reactions at high pressures and high temperatures. The second is a continuation of an investigation on the oxidation of hydrocarbons and the inhibition by various substances, such as antiknocks, and has led to a study of the behaviour of the two forms of hydrogen (ortho and para) at surfaces. The third is a continuation of researches on the thermal properties of vapours, an accurate determination of the vapour pressure of steam having recently been accomplished in an apparatus designed by the late Prof. H. L. Callendar at South Kensington.

I am interested in the application of thermodynamical studies to every branch of activity, for example, fuel conservation, heating and ventilating, economical use of heat in chemical processes, etc., and think that more attention should be paid to such studies. In Germany, within the Technische Hochschule at Munich, there is an institute under Prof. Knoblauch devoted to such work, and I should like to see something similar in Great Britain.

Oct. 14, 1891.—JAMES GRAY, F.R.S., University reader in experimental zoology, Cambridge.

A study of the metachronal rhythms of ciliated epithelia has led to an attempt to analyse similar phenomena in muscular systems, and I am at present interested in the mechanical principles underlying the propulsion of fish and of annelid worms, the muscular systems of which exhibit well-defined rhythms. By means of a suitable camera it is possible to record such movements with accuracy.

In association with others, an attempt is being made to analyse the osmotic properties of the membrane which surrounds the egg of the trout. It is now possible to define its permeability to ions with considerable accuracy, but a complete interpretation of the results must depend on the degree to which the membrane is found to be permeable to water.

Oct. 14.—Dr. MARIE CARMICHAEL STOPES, formerly lecturer in palæobotany at University College, London, and at Victoria University, Manchester, fellow of University College, London.

In conjunction with the Coal Research Club, I am continuing to probe into the ultimate nature and composition of the constituents of coal, which affords very complex problems in spite of the great increase in knowledge on all sides in recent years.

As founder and president of the Constructive Birth Control Society and Clinic, I am carrying on research and observation in various aspects of human sex-physiology, and accumulating data about very large numbers of women (approximately 15,000 to date at the Clinic).

In my holidays at Portland, while founding the Portland Island Museum, I am accumulating Cycadoidea and searching for Jurassic Angiosperms.

Societies and Academies.

PARIS.

Academy of Sciences, Aug. 10.—**A. Lacroix**: The recent (June 27, 1931) fall of an asiderite meteorite in the extreme south of Tunis. The term asiderite is applied to meteorites free, or practically free, from metallic iron. The meteorite now described fell near Tatouine and is of Tschermak's diogenite type, only four of which have hitherto been observed.—**Charles Achard, Augustin Boutaric, and Arthur Arcand**: The physical properties of the serum proteins and of the hydropic serosities in lipoid nephrosis. In lipoid nephrosis the colloidal granules of the serum have lost the property of hydration on heating. The same anomaly is shown by the proteins separated from this serum. Hence in this disease there are not only quantitative modifications of the various proteins but also modifications in the physical properties of these proteins.—**D. Belorizky**: The convergence of the series in the solution of the problem of three bodies given by Sundmann.—**R. de la Boulaye and G. Balme**: The velocity of propagation of musical sounds. The velocity of musical sounds in the open air is constant and independent of the frequency, but in a tube of one metre diameter the velocity varies slightly with the frequency. Part of this work was carried out by the late Th. Vautier.—**Pierre Auger and Charles Lapicque**: Variation in the spectrum of the sensibility of cuprous oxide cells. The photoelectric cell used in this investigation consisted of a layer of cuprous oxide on a copper plate, the former being covered by a thin transparent film of metal obtained by cathode sputtering. The maximum sensibility was shown for light of λ5000 A.—**G. Darzens and André Lévy**: The constitution of the methyl ether of butyl-*m*-cresol and of its dinitro derivative, ambrette musk.—**Jean Roche and Albert Bendrihem**: The combination of globin with hæmatins of various origins. Hæmatin extracted from helicorubin, from yeast, or from cytochrome *c* combines with globin, giving a pigment spectroscopically identical with that of blood.—**F. Rathery, Mlles. S. Gibert and Y. Laurent**: The liver and muscle glycogen in the nephrectomised dog.

Aug. 17.—**Camille Matignon**: Commercial nitrates of lime. The author in a recent paper put forward the view that calcium nitrate, now manufactured on the large scale, should not be regarded as a dangerous chemical from the point of view of storage or transport. It only becomes dangerous when heated in contact with a combustible material. An account is given of a recent fire at Oslo, involving 70 tons of calcium nitrate, confirming the author's conclusions.—**L. Blaringhem**: The experimental production of spelt wheats (*Triticum spelta*) starting with a wild plant (*Ægilops ventricosa*).—**Paul Delens**: Affine geometry of congruences of curves.—**Maurice Golaz**: A new principle of hydraulics. This is given as follows: the stable form of flow is that which, under given external conditions, develops the maximum power in the section where parallel flow is established.—**René Dubrisay and René Pallu**: The photochemical oxidation of sulphur. The results of the experiments described by the authors are consistent with the view that the primary product of the oxidation of sulphur by air under the action of ultra-violet light is pentathionic acid. This decomposes readily, giving sulphuric acid, hydrogen sulphide, sulphur dioxide, and sulphur.—**J. Giuntini**: The spectrographic study of the compounds of tartaric acid and copper. The results show that copper tartrate is a salt in which a part of the copper is present as a complex compound. This confirms the results of Darmois.—**Justin Dupont and Jean Jacques Guerlain**. The dry distillation of Peru balsam. The hydrocarbons and phenolic ethers obtained are similar to those obtained by the dry distillation of Tolu balsam.—**André Meyer and Robert Vittenet**: The azo colouring matters derived from homophthalimide.—**Marcel E. Denaeyer**: Director lines and geological evolution of French Equatorial Africa and the Cameroons.—**A. Dauvillier**: Polar auroræ and the cosmic rays.—**Paul Wintrebert and Ouang-Te-Yo**: The digestion *in vitro* of the white and of the gluten of the egg of oviparous plagiostomes (*Scylliorhinus canicula*) by the frontal gland of the embryo.

ROME.

Royal National Academy of the Lincei, March 1.—G. Armellini: The theory of the variability of the family of Mira Ceti. As judged by the eye, the radiation of this star varies in the proportion of 200 : 1 or 100 : 1, whereas measurements with the bolometer or thermoelectric pile indicate the ratio 3 : 1 or 2 : 1. The values generally accepted for its extreme temperatures, namely, 2300° and 1800°, involve a very marked divergence between theory and observation. To obtain calculated results in good agreement with the observations, lower values, namely, 1500° and 1100°, must be adopted for the extremes, but these may give rise to difficulties in other directions. If these values are regarded as inadmissible, the observed phenomena are explainable only by associating the temperature variations with a variation in the atmospheric transparency, in accordance with the veil theory, advanced by Merill and supported by Hopmann.—**Q. Majorana**: New photoelectric investigations. It was found previously that, when light, periodically interrupted, falls on the first triode of an amplifying group, the telephone of the amplifier repeats the sound corresponding with the frequency of interruption of the light. Various new observations, now described, throw some light on this phenomenon.—**Gian Antonio Maggi**: Demonstration of a property pertaining to the theory of the potential function of surfaces.—**G. A. Blanc**: Certain properties of the silica remaining after attacking leucite with acids. A method is described for separating, from the liquid obtained on treating leucite with an acid, the residual silica existing as a colloidal suspension, and an explanation of the phenomena accompanying such separation is advanced.—**L. Petri**: A method for detecting the exceptional presence of mercury in vegetable tissues. The use of mercury salts as an external fungicide for seeds, particularly those of cereals, is followed by absorption by the plant of traces of mercury from the soil, with the result that the functional activity of the plant is stimulated. The presence of traces of mercury in plant material may be detected by treating the plant juices with hot hydrochloric acid and afterwards leaving a piece of silver foil immersed in the solution for some hours. Any slight amalgamation of the silver which occurs is readily revealed either by exposing the foil to iodine vapour or by heating the foil gently before a spectroscope.—**T. Boggio**: Relation between the Riemannian homographs relative to two spaces in conform representation.—**Giacinta Andruetto**: Relation between Riemann's symbols relative to two varieties, one immersed in the other.—**N. Théodoresco**: Dirac's system of equations with partial derivatives.—**Ugo Broggi**: Resolution of algebraic equations.—**R. Calapso**: Synthetic studies of differential projective geometry.—**R. Serini**: Propagation of transverse vibrations in a finite string with resistance of the medium.—**M. Maggini**: A direct method for determining the interferometric λ eff.—**G. Bernardini**: The technique of magnetic spectrographs for slow electrons.—**Paolo Straneo**: The unitary theory of gravitation and electricity. (1) Physico-geometric foundations for a deduction of the equations of the field.—**M. Amadori**: Mercury derivatives of divalent bromophenols. Various mercuric compounds of the di- and tri-bromo-derivatives of pyrocatechol and resorcinol are described. These compounds are formed by the replacement of two hydrogen atoms by one mercury atom, but whether these two hydrogen atoms are both hydroxylic, or one hydroxylic and one united to a carbon atom, is as yet undecided.—**G. A. Barbieri**: Molybdo-octocyanides. On the basis of various reactions shown by the red substances obtained by treating potassium molybdo-octocyanide with hot, concentrated nitric acid, the author does not consider the formula $H[MoO_2(CN)_2.2H_2O]$ suggested for this substance by Bucknall and Wardlaw (1927) to be justified.—**A. Quilico** and **M. Freri**: Azopyrrole blacks (4). Details are given of the experiments on which the results given in note (3) are based.—**L. De Marchi**: Fridtjof Nansen. A memorial notice, containing an account of Nansen's polar expeditions and discoveries.

Diary of Societies.

FRIDAY, October 9.

Royal Society of Medicine (Clinical Section), at 5 30.

Malacological Society of London (at Linnean Society), at 6.—E. Ashby: Notes on Chitons from Port Alfred, South Africa, collected by Lt.-Col. W. H. Turton during 1930.—A. E. Ellis: A Reclaimed Saltmarsh.—G. C. Robson: Further Observations on the Distribution of *Cochlicella acuta*.—L. R. Cox: *Sycostoma* a renamed Genus of Lower Tertiary Gastropoda.—H. B Moore: The Systematic Value of a Study of Molluscan Fæces.—R. Winckworth: Notes on *Nucula nitida*.—Lt.-Col. A. J. Peile: Some Notes on Radulæ.

Oil and Colour Chemists' Association (Manchester Section) (at College of Technology, Manchester), at 7.—J. Barker: The Transference of Colour Processes from Laboratory to Works (Lecture).

Manchester Association of Engineers (at Engineers' Club, Manchester), at 7.15.—C. E. Stromeyer: Presidential Address.

Junior Institution of Engineers, at 7.30.—E. D Gill: Office Engineering.

Keighley Textile Society (jointly with Keighley Association of Engineers) (at Queen's Hotel, Keighley), at 7.30.—G. A. Rix: Faraday's Life and Work.

Institute of Metals (Sheffield Local Section) (jointly with Sheffield Society of Engineers and Metallurgists) (in Applied Science Department, Sheffield University), at 7.30.—Dr. W Rosenhain: Gases in Metals.

Institution of Production Engineers (at Society of Motor Manufacturers and Traders, 83 Pall Mall) (Annual General Meeting), at 7.30.—J. G. Young: Distribution and Production.

Society of Chemical Industry (Chemical Engineering Group) (at Chemical Society), at 8.—D. M. Wilson: The Manufacture and Testing of Asphalt Paving Material.

Royal Society of Medicine (Ophthalmology Section), at 8.30.

Oil and Colour Chemists' Association (Manchester Section) (at College of Technology, Manchester).—J. Barker: Transference of Colour Processes from Laboratory to Works.

MONDAY, October 12.

Institute of Metals (Scottish Local Section) (at 39 Elmbank Crescent, Glasgow), at 7 30.—L. Short: Some Random Reflections on Industrial Problems and Economics

TUESDAY, October 13.

Society for the Study of Inebriety (at Friends' House, Euston Road), at 4.—Viscount Brentford: How the Alcohol Question concerns the Duties of the Home Office (Norman Kerr Memorial Lecture).

Institution of Petroleum Technologists (at Royal Society of Arts), at 5 30.—H. L. Allen: Sweating of Paraffin Wax.

Institute of Marine Engineers, at 6.—D. MacNicoll: Safety Valves.

Institute of Metals (Swansea Local Section) (at Y.M.C.A., Swansea), at 6.15.—A. M. Kempson: Chairman's Address.

London Natural History Society (at London School of Hygiene and Tropical Medicine), at 6.30.—H. J. Burkill: Plant Galls: More Galls to be looked for.

Institution of Heating and Ventilating Engineers (Associate Members' and Graduates' Section) (at Borough Polytechnic), at 7.—E. M. Ackery: Thermal Storage for Central Heating.

Institute of Metals (North-East Coast Local Section) (at Armstrong College, Newcastle-upon-Tyne), at 7.30.—J. W. Craggs: Chairman's Address.

Quekett Microscopical Club (at 11 Chandos Street, W.1), at 7.30.—Dr. C. D Darlington: Microscopic Studies of the Mechanism of Heredity.

Institution of Welding Engineers (North-Western Branch) (at College of Technology, Manchester), at 7.30.—L. B. Wilson: Application of Resistance Welding.

Royal Anthropological Institute, at 8.30.—Miss Winifred Blackman: Medicine and Magic among the Egyptian Fellaheen.

WEDNESDAY, October 14.

Institution of Engineering Inspection (at Royal Society of Arts), at 5.30.—P. R. Coursey: Some Applications of Condensers to Electric Power Circuits.

Newcomen Society for the Study of the History of Engineering and Technology (at Science Museum, South Kensington), at 5.30.—H. W. Dickinson: Jolliffe and Banks, Contractors; also other Papers.

THURSDAY, October 15.

Optical Society (at Imperial College of Science), at 7.30.

Chemical Society, at 8.—E C. S. Jones and J. Kenner: The Interaction of 2:6-dichloro-4-methylquinitrol with Methyl and Ethyl Alcohols.—H. D. K. Drew, F. W. Pinkard, W. Wardlaw, and (in part) E. G. Cox: The Structure of the Isomeric Platinous Diammino Chlorides. Discovery of a Third Isomeride.—H. D. K. Drew, F. W. Pinkard, and W. Wardlaw: The Structure of the Simple and Mixed Plato Tetrammine Dihalides.—A. P. T. Easson and Prof. F. L. Pyman: Amidines of Pharmacological Interest.

Royal Society of Medicine (Neurology Section), at 8.

Royal Society of Tropical Medicine and Hygiene (at London School of Hygiene and Tropical Medicine), at 8.15.—W. H. Gray and Dr. J. W. Trevan: Experiments on Antimony Compounds used in the Treatment of Bilharzia and Kala-azar

Institute of Brewing (Midland Counties Section) (at White Horse Hotel, Birmingham).—S. Myer: The Season's Hops.

Institute of Brewing (North of England Section) (at Midland Hotel, Manchester).—W. J. Watkins: Notes on Enclosed Wort Refrigeration. Part II

Institute of Brewing (Yorkshire and North-Eastern Section) (at Queen's Hotel, Leeds).—E A. Braithwaite: Stainless Steel and its Practical Application

Royal Aeronautical Society.—H. Sutton: The Protection of Metals in Aircraft Construction.

Institution of Welding Engineers (at Institution of Mechanical Engineers).—E. B. Partington: Autogenous Welding of Lead and its Alloys, Ancient and Modern.

FRIDAY, October 16.

Physical Society (at Imperial College of Science), at 5

Institution of Mechanical Engineers (Special General Meeting), at 6.—Approval of Draft By-Laws.

West of Scotland Iron and Steel Institute (at Royal Technical College, Glasgow), at 7.15.—J. Bird: Presidential Address.

Junior Institution of Engineers, at 7.30.—C. C. Berger: The Characteristics of Commercially Pure Iron.

Nelson Textile Society (at Nelson Technical College), at 7 30.—J. Loxham: Wonderful Products from Coal.

Royal Society of Medicine (Obstetrics and Gynæcology, Medicine, and Psychiatry Sections), at 8.15.—Discussion on Medical Indications for Premature Termination of Pregnancy.

North-East Coast Institution of Engineers and Shipbuilders (Annual General Meeting) (at Literary and Philosophical Society, Newcastle-upon-Tyne).—J. McGovern: Presidential Address.

PUBLIC LECTURES.

SATURDAY, October 10.

Royal Institute of British Architects, at 3.—C. Williams-Ellis: Architecture? What's the Use?

Horniman Museum (Forest Hill), at 3.—Miss M. A. Murray: Egyptian Beliefs in the Hereafter.

MONDAY, October 12.

University College, at 5.—Dr. R. J. Lythgoe: The Physiology of the Sense Organs. (Succeeding Lectures on Oct. 19 and 26 and Nov. 2, 9, and 16.)

Royal Anthropological Institute (at University College), at 5.30.—The Marquess of Zetland: The Races and Cultures of India: India Past and Present.

University of Leeds, at 8.—Prof. A. Gilligan: The House we Live in.

TUESDAY, October 13.

University College, at 3.—Prof. B. Ashmole: Greek Sculpture.

London School of Hygiene and Tropical Medicine, at 5.—Sir George Newman: The Rise of Preventive Medicine (Heath Clark Lectures). (Succeeding Lectures on Oct. 15, 16, 20, and 22.)

Bedford College for Women, at 5.15.—Miss Hosgood: The Geography of Cities.

University College Hospital Medical School, at 5.15.—Prof. J. C. G. Ledingham: Resistance to Infection, Natural and Induced. (Succeeding Lecture on Oct. 20.)

King's College, London, at 5.30.—Sir Bernard Pares: Russian History to 1861: Country and Peoples.

University College, at 5.30.—Prof. K. Buhler: Theory of Language and Psychology of Speech. (Succeeding Lecture on Oct. 15.)

British Institute of Philosophy (at University College), at 8 15.—Sir James Jeans: The Mathematical Aspect of the Universe.

WEDNESDAY, October 14.

Royal Institute of Public Health, at 4.—Sir Ernest Graham-Little: The Health of the London Citizen.

London School of Economics, at 5.—Dr. R. S. Williams: The Production, Distribution, and Nutritional Value of Milk. (Succeeding Lectures on Oct. 21 and 28.)

King's College, London, at 5.30.—Prof. E. V. Appleton: James Clerk Maxwell.

University College, at 5.30.—Dr J. Needham: Speculation, Observation, and Experiment, as illustrated by the History of Embryology. (Succeeding Lectures on Oct. 21 and 28 and Nov. 4.)

THURSDAY, October 15.

London Hospital Medical College, at 4.15.—Prof. A. J. Hall: Chronic Epidemic Encephalitis (Schorstein Memorial Lecture)

King's College, London, at 5.—Dr. J. A. Hewitt: Metabolism of the Carbohydrates and Fats. (Succeeding Lectures on Oct. 22 and 29 and Nov. 5.)—At 5.30.—Dr. Eveline Martin: West Africa of To-day: The Entrance to British West Africa; the West Indies and the Gambia.

University College, at 5.—Prof. E. A. Gardner: Poet and Artist in Greece.

FRIDAY, October 16.

University College, at 5.—Dr. L E. Bayliss: The Respiratory Functions of the Blood. (Succeeding Lectures on Oct. 23 and 30 and Nov. 6.)

Institution of Electrical Engineers, at 5 30.—E. C Crittenden: The Measurement of Light: its Basis and its Significance. (Succeeding Lectures on Oct. 21, 23, 26, and 28.)

SATURDAY, October 17.

Royal Institute of British Architects, at 3.—H. S. Goodhart-Rendel: Some Opinions upon Furniture and Decoration

Horniman Museum (Forest Hill), at 3.30.—H. N. Milligan: Success and Failure in the Animal World

CENTENARY.

Friday, October 9.

Michael Faraday Centenary Celebration (in City Hall, Newcastle-upon-Tyne), at 7.—Dr. W. M. Thornton: Faraday and his Successors—the Growth of an Idea.

Prevention of Atmospheric Pollution.

FROM time to time abnormal visitations like the heavy fog in the valley of the Belgian Meuse, Dec. 3–5, 1930, resulting in sixty-five deaths, emphasise the dangers of atmospheric pollution. Although John Evelyn, writing in 1661 in "Fumifugium"—the first smoke abatement pamphlet—clearly portrayed the noxious effects of an impure atmosphere, efforts at smoke abatement have not progressed at anything approximating to the rate at which sources of contamination have multiplied during the last two centuries.

In the Meuse fog tragedy, the evidence indicates that the poisonous fumes from industrial chimneys which became imprisoned in the fog were mainly responsible for the casualties. Similarly, Dr. Turner attributes the fog catastrophe in the industrial region south of Luttich to the presence in the atmosphere of fluorine compounds—hydrogen fluoride, silicon fluoride, or possibly silicofluorohydrins—from some industrial process.

It is only under abnormal atmospheric conditions when the scavenging of the air by turbulence is reduced that the menace to health which the emission of poisonous industrial fumes represents is clearly demonstrated. The aggregate number of annual deaths of both young and old which can be definitely attributed to the filthy atmosphere in our smoke-ridden towns is very much greater than those associated with such exceptional conditions. The increase in mortality rates from pneumonia, bronchitis, and other respiratory diseases associated with every spell of foggy weather, and the acceleration of invalidism and death owing to the acid condition of the atmosphere and the exclusion of direct sunlight, pass almost unnoticed, although John Evelyn's comment is as pertinent now as in Restoration times: "The consequences then of all is, that . . . almost one half of them that perish in London dye of phthisical and pulmonic distempers: that the inhabitants are never free from coughs and importunate rheumatisms, spitting of impostumated and corrupt matter: for remedy whereof, there is none so infallible, as that, in time, the patient change his Aer, and remove into the country".

Litigation concerning the Barton power station near Manchester has directed attention to the dangers of the emission of fumes as distinct from smoke. The remarks of the judges in this case appear to have had salutary effect and roused authorities in time to the importance of the new power stations consuming their own smoke. Not only has an eminent architect, Sir Gilbert Scott, been consulted on the design of the huge producing plant at the new Battersea station, but as a result of scientific research new methods of treatment of the fumes have been devised by Dr. G. L. Pearce and his assistants, which ensure the ready conversion of the sulphur dioxide into sulphuric acid or other products which are easily removed. The Minister of Transport has stated that as a result of the precautions, on which the Electricity Commissioners have insisted, only a negligible amount of sulphur will be emitted.

The problem of reducing or preventing the emission of smoke from factories is relatively simple, being mainly economic. Corrosion of plant and buildings and the heavy expense of cleaning and maintenance, which are the direct result of the deposition of a corrosive mixture of soot, tar, mineral ash, and sulphurous acid from the atmosphere, are rapidly impressing on industry the economic advantage of eliminating the pollution at its source. The realisation that smoke is largely the result of inefficient combustion has led to a widespread application of the principles of fuel technology in industry, which have already materially reduced the proportion of industrial smoke, and for many industrial purposes coke and other forms of smokeless fuel are largely used in place of raw coal.

The progress made in smoke abatement in regard to industry, and the fact that the most dangerous atmospheric impurities are derived from industrial sources, tend to obscure the importance of the domestic factor. By far the greater proportion of atmospheric pollution as smoke comes from the domestic sources in consequence of our preference for the open coal fire. In London and Glasgow, domestic fires, for example, account for 75 per cent of the deposited solid matter. Unfortunately, the minimising of smoke emission from such sources is a much more difficult problem, and scarcely capable of legislative control.

As the latest report of the Standing Conference of Co-operating Bodies for the Investigation of Atmospheric Pollution under the scheme organised by the Department of Scientific and Industrial Research indicates, however, owing to the importance of the domestic factor, further progress in the improvement of atmospheric conditions in many of our large towns is largely conditioned by the extent to which gas, electricity, or smokeless fuel replaces raw coal for heating in the house. Much more might be done in this field, particularly in regard to local housing schemes. The importance of the domestic factor renders it highly desirable that 'garden suburbs' and similar schemes should not involve a continuous extension of the radius of serious atmospheric pollution. Houses in such schemes might be wholly or mainly equipped for heating by methods other than that of burning raw coal.

The prevention and control of atmospheric pollution in its range and complexity is characteristic of those modern problems which require the leadership of science for their solution. The production of a satisfactory smokeless fuel is still in an experimental stage, although such fuels as coalite have already met with a certain amount of public approval. The production of these fuels at a popular price has yet to be achieved, and its possibility is openly challenged in some quarters. It will at best in part be determined by the value and successful exploitation of the by-products of the low temperature carbonisation process, especially the tar oils. The successful utilisation of the large quantities of such tars which would be available if the low temperature carbonisation fuels absorb any considerable proportion of the domestic market is a major industrial and scientific problem. Equally complex is the reaction on the coal industry of a large demand for the grades of coal used for such carbonisation processes, and a concurrent reduction in the demand for high grade house coal.

The whole problem is intricate and in every aspect demands the application of scientific methods, if the necessary elasticity and balance are to be obtained. In few fields could premature legislation have a more mischievous effect. Since April 1927 the Department of Scientific and Industrial Research has been responsible for co-ordinating observations of atmospheric pollution all over the country, and for the prosecution of research into the nature of this pollution, and of the best methods for measuring it. An Atmospheric Pollution Research Committee has undertaken a fairly extensive programme of research, and investigations on the lateral distribution of atmospheric pollution which are being carried out at Norwich have attracted particular attention.

There are indeed only three places in England and Wales with populations above one quarter of a million which do not appear on the list of co-operating bodies undertaking the investigation of atmospheric pollution. These are Bristol, Nottingham, and West Ham. The absence of Nottingham from the list gives pertinence to the record in the annals of Dunstable (quoted by Shaw and Owens in "The Smoke Problem of Great

Cities ") that, in the year 1257, Eleanor, Queen of Henry III., was obliged to leave the town of Nottingham, where she had been sent to stay during the King's absence in Wales, and removed to Tutbury Castle instead, owing to the smoke of the sea coals.

Apart from direct research on atmospheric pollution, scientific workers are making important contributions, as already indicated, in fuel technology and research, including methods for the precipitation and combustion of smoke particles as emitted, the design of new industrial plant, and the control of industrial processes. The efficient application of the results of research in this field largely depends on them. Suggestions for the improvement of industrial processes, especially the elimination of noxious vapours, are mainly due to their observations and investigations. Their participation in the educational campaign that is required should assist the removal of prejudices and correct the extravagant statements which are frequently made on behalf of new products. Observations made in their private capacity when adopting the smokeless methods of heating will materially assist in the improvement of the quality of the smokeless fuels or types of electric or gas fires in use. Progress in domestic heating can be greatly accelerated by scientific co-operation along such lines, and if such co-operation were more widely established a salutary check would be available on the activities of those who, by offering inferior smokeless fuel to the public, are prejudicing its sale. From every angle the prevention of atmospheric pollution is one that demands the support of all scientific workers, and not the least important contribution they can make is that of example.

Electric Pendulum Clocks.

Electric Clocks. By F. Hope-Jones. Pp. xv + 261. (London: N.A.G. Press, Ltd., n.d.) 12*s.* 6*d.* net.

THE fact that there is a foreword by the Astronomer Royal is the best evidence that this is a serious work. The Astronomer Royal indicates that it is characteristic of the author in manner and style, as I shall have occasion to do in this notice. I have at once discarded the customary third person and have begun in the first. When dealing with the later portion of the book, which relates to matters which I have followed so closely throughout their progress, any attempt to discuss the matter and express my own views and those of others would lead to too great a complication, if the conventional third person were to be used.

Let me at once say that the author writes as the 'high priest' who knows that his religion is the only true religion and his faith the only true faith: from one end of the book to the other he preaches the one doctrine as to the way to follow to attain the perfect clock; all other ways are vain, and lead, if not to perdition, to less perfect results. Like St. Athanasius, his faith is clear and emphatic, and the conclusion of 'St. Hope-Jones' is like that of his predecessor and in almost the same words, " This is the clock faith: which except a man keep faithfully he cannot be safe ". There is, however, this difference, that whereas the faith of St. A. requires much practice before it can be believed properly, that of 'St. H.-J.' appeals directly to reason and is quite easy to believe the first time. In fact, with thed amnation clause somewhat tempered, I am prepared to subscribe to it myself.

The title appears to me slightly misleading. An electric clock which vies in accuracy with the most perfect clock known, to which the whole book leads up, is not even mentioned. This is the quartz crystal clock perfected by Mr. W. A. Marrison, of the Bell Telephone Company's research laboratory, without which the real perfection of the champion clock would not and could never be known. A correct title would be " Electric Pendulum Clocks ", that is, clocks depending on gravity, as distinct from electric clocks with balance wheel control, which, if they exist, are quite unimportant, and from the quartz crystal clock which depends on the electro-mechanical properties of the crystal and is independent of gravity. It is this final comparative check on the going of *the* champion clock (Shortt) described in March last by Prof. E. W. Brown and Mr. Dirk Brouwer at the Royal Astronomical Society, of which publication has only recently taken place, that has shown the high-water mark of performance which has been reached. Mr. Hope-Jones may well be proud of the very important share that he has had in the development of an electric pendulum clock of unapproached perfection.

Mr. Hope-Jones traces the history of electric clocks from the earliest by Wheatstone and Bain, and his account is the more valuable because not only has he the whole history at his finger-ends, but also he brings to bear his very complete understanding of the conditions of success, which have made the synchronome and the Shortt clocks what they are, to examine critically the designs of earlier clocks. The peculiarity of the electric clock is that as soon as a student or a mechanic has learned about an electric circuit, an electromagnet, and a contact, he straightway invents an electric clock. As we are told, he is probably entirely ignorant of what has been done, of what is wanted, and of the precautions necessary if all the pitfalls are to be avoided. Proposals for electric clocks are as the sand on the seashore. A minute fraction of these have ever seen the light, but these still are legion. Those who remember the electric experiments that we used to make fifty to sixty years ago will realise at once one of the many causes of failure. The lightest contact of a platinum wire backed by the 'current of one Daniel cell' was found to respond, but except for the purpose of a temporary experiment, it would inevitably fail if it were depended on for continued service. Eighty-six thousand four hundred of such contacts every day, day by day and year after year, were impossible and useless, and it is very difficult for those conducting electrical experiments in these days with new materials and lots of volts to visualise the early conditions. Take, for example, the success of the Strowger system (to mention only one) for automatic telephones, where every call requires the faithful response of a very large number of contacts; such would have been impossible with the delicate means available for early inventors.

One of the points insisted upon by the author, not once but all the time, is that an electric contact in an electric clock must be almost of a violent kind; it must at least be very firm, to be any good, and he gets this by using the contact as the operative pressure point, so that hesitation is impossible. The light and hesitating contact invariably fails. It was no doubt the experience of repeated failure in one electric clock after another that led Lord Grimthorpe to his adverse opinion. Those who knew him will remember that he, too, had very definite views on clocks and bells and architects and things, and that he never seemed shy of expressing himself very definitely. Mr. Hope-Jones quotes these passages from his well-known book, "Clocks, Watches and Bells": "These clocks never answered in any practical sense, nor would anything but the strongest evidence, independent of the inventor, convince me that any independent pendulum directly maintained by electricity can succeed in keeping good time for any considerable period. . . . And anyone who sets to work to invent electrical clocks must start with this axiom, that every now and then the electricity will fail to lift anything, however small."

Well, this was a proper and natural conclusion at the time, and when Lord Grimthorpe showed me his gravity escapement regulator in the late 'seventies, that was, in his opinion, the last word in clock design. Jumping, then, the whole history of electric clocks in the interval, it is interesting to find the electric clock on a pinnacle of perfection such as we now see.

It would be tedious, even were space available, to refer chapter by chapter to the author's account of all the clocks discussed. It will be more useful to pick out a few examples which have an interest of their own or which mark steps on the road to the Shortt clock.

One of the early attempts to make a high precision clock was that by Sir David Gill at the beginning of the present century. He aimed at a free pendulum maintained at a uniform temperature and low pressure. The free pendulum was nursed by a slave pendulum of rather less period, which was released by an electric contact following the impulse on the free pendulum and then caught and held until it was released again. Sir David showed me the clock in its place at the Cape Observatory and spent a long time going into the details. I did not like the idea of the slave pendulum being arrested every two seconds and then starting again. Any slave clock should be a complete going clock, but it was difficult to criticise an instrument so dear to the heart of that delightful man. I felt that there were so many things to see to, that it would be a full-time occupation for an attendant to keep it in order.

The first slave pendulum clock which was a complete clock that I ever saw was that shown by Mr. C. O. Bartrum at a meeting of the Physical Society in or about 1914. Here the free pendulum sent a synchronising message to the slave every minute instead of every two seconds, while on the other hand the slave with a somewhat clumsy lost-time device sent an impulse message to liberate an impulse lever to keep the free pendulum going. Mr. Bartrum's ideas were good but his technique was poor, and this is severely criticised by the author.

We learn from Mr. Hope-Jones that the first free pendulum was one described by R. J. Rudd in the *Horological Journal*, 1898, 1899, but important as his contribution was, he did nothing with it. However, it is interesting to know that Mr. Hope-Jones acquired Rudd's clock and presented it to the Science Museum at South Kensington.

Early in the present century, Sir Henry Cunynghame made a number of experimental clocks. His aim was, as Airy's had been long before, to maintain the oscillations of a seconds pendulum by means of a chronometer escapement acting on the pendulum at the middle only of its swing. The escapement was placed at the lower end of the pendulum, a position advantageous for operation but decidedly inconvenient. Mr. Hope-Jones and Sir H. Cunynghame collaborated, and the outcome of this was a sort of combination of a most important prior invention of Mr. Hope-Jones, which he had described in 1895, and some of the features of Sir H. Cunynghame's clock. The important invention referred to was the use of the electrical contact to transmit mechanically a strong impulse, thus ensuring unfailing action. Further progress found the impulse operation removed from the lower end of the pendulum to a point near the upper end. Another important feature was the introduction of a count wheel which allowed an impulse to be applied every thirty seconds only, and the synchronome clock as we have known it for so long as a most successful instrument came into being. In this the Hope-Jones articles of faith are all to be found with another of his really beautiful mechanical devices, the form of ratchet drive by which all the dials operated by the master clock make their half-minute jumps without the possibility of overshooting or failing. They are not silent, and an irritable listener in a bedroom might want to throw a boot at the dial.

The synchronome system has been so great a success that the author may well congratulate himself that he was not discouraged by Lord Grimthorpe but went his own way. He may also congratulate himself in that it is the synchronome clock on which Mr. Shortt has grafted his invention. Mr. Shortt has a free pendulum in a nearly vacuous case—which should be deep underground but never is—subject to an impulse every half minute. The impulse lever is liberated by a slave clock which is a synchronome master clock, and the impulse lever, after acting on the free pendulum, drops and makes a firm contact which resets the impulse lever through the intervention of an inertia piece, and it also sends a current to the hit-and-miss device which keeps the synchronome pendulum in exact step. This latter device is most fascinating to watch, and people are apt to think that that is all that Mr. Shortt has done. The author shows what a long series of devices Mr. Shortt experimented with before he got his inertia delay action to ensure good contact and the right phase. Not the least important feature in the Shortt clock is the unfailing accuracy of response of the half-minute time signals to the position of the free pendulum. A mere contact operated by a slow-moving wheel would be quite useless except for rating over long periods. The lever actually dropped after its impulse on the free pendulum indicates the time correctly to a thousandth of a second at least, as proved by the operation of the Loomis spark chronograph, and if the hundred and twenty records in an hour are taken the time is known to the ten-thousandth.

The marvellous improvement in timekeeping effected by the Shortt clock was first recognised by the Astronomer Royal for Scotland. Shortly after, the Astronomer Royal at Greenwich found that it left all other clocks far behind, but neither of them had the means for ascertaining the full perfection of the clock. For these means the world is indebted jointly to Mr. Loomis of Tuxedo Park, New York, and to Mr. W. A. Marrison, already mentioned. Mr. Loomis obtained in the year 1928 three Shortt clocks and set them going in a constant temperature enclosure, and I had the good fortune to assist him in setting up the first. Owing to the uniformity of temperature in the clock room (±0·02° C.), these clocks have a better chance of proving their value than many others; but even though they might go better, the degree of perfection indicated in the analysis by Prof. E. W. Brown (of Yale) and Mr. Dirk Brouwer could never have been ascertained without the ceaseless record of each clock every half minute by the Loomis spark chronograph. Even so, the perfection of going could not be known without the use of the quartz clock in New York connected by private wire with Tuxedo, forty miles away. The quartz clock 'ticks' 100,000 times a second, and 1000 time signals a second are sent by it along the line. These are made to actuate the spark arm and the motor which feeds the paper of the spark chronograph. When in the United States, I had the opportunity of meeting Mr. Marrison and hearing from him the whole story of his quartz clock, and of seeing it, in so far as it is possible to see anything. Mr. Marrison's account of this research, published by the Bell Telephone Co. the following year, appears to me to be of such outstanding interest that the Physical Society of London might well reprint it, with Mr. Marrison's permission.

Now the degree of perfection to which I have been leading up is no less than the certain observation of a six-hourly fluctuation of rate of the pendulum clocks under the influence of the moon's gravity. This is vouched for by Prof. Brown and Mr. Brouwer, and it needed the unvarying rate of the quartz clock and the thousandth of a second accuracy of each record of each clock every half minute to bring this out. At the latitude of Tuxedo the calculated accumulated error of a pendulum clock at lunar six o'clock is $-0{\cdot}000153$ sec. as compared with lunar noon and midnight, and this is certainly shown by the clocks. There are, of course, other effects of the moon, but the agreement between the gravitational disturbance of the clocks observed and calculated leads the authors of the paper to conclude that these others very largely neutralise one another. They give the following way of realising what the figures mean. "The same effect would be produced if the clocks were given a vertical oscillation with a semi amplitude of 2·5 inches and with the same period. An amplitude of 1 inch could be detected in a month's observations."

This is such a triumph that the four who have made it possible—Hope-Jones, Shortt, Loomis, and Marrison—might well believe that the limit has been reached, and rest; but it is certain that none of them will. C. V. Boys.

Fluid Motion.

(1) *Handbuch der Experimentalphysik.* Herausgegeben von W. Wien und F. Harms. Unter Mitarbeit von H. Lenz. Band 4: *Hydro- und Aerodynamik.* Teil 1: *Strömungslehre und allgemeine Versuchstechnik.* Herausgegeben von Ludwig Schiller. Bearbeitet von J. Ackeret, A. Betz, J. M. Burgers, A. Busemann, H. Falkenhagen, H. Mueller, H. Peters, L. Prandtl, H. Schmiedel, O. Tietjens, W. Tollmien. Pp. xii + 730. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1931.) 68 gold marks.

(4) *Flow and Measurement of Air and Gases.* By Alec B. Eason. Second edition, thoroughly revised. Pp. xii + 254. (London: Charles Griffin and Co., Ltd., 1930.) 20*s*. net.

THE study of fluid motion, both theoretically and experimentally, has made rapid progress during the last two decades. On one hand, the general recognition of the laws of dynamical similarity has led to a better appreciation and to a closer co-ordination of the experimental results, and on the other hand, the introduction of certain simplifying assumptions by Prandtl has led to a development of hydrodynamic theory which is remarkable both for the width of its applicability and for the accuracy of its predictions. The study of the boundary layer by theoretical analysis and by a highly developed experimental technique has explained many phenomena of fluid motion which were hitherto obscure, and the extension of the conception of a perfect fluid to include the possibility of circulation round a body, accompanied by a system of trailing vortices, has led to successful theories of the behaviour of the wings and propeller of an aeroplane.

(1) This collective work gives an excellent account of the present position of the theory of fluid motion and of the experimental methods which have been developed for studying the motion. From this wealth of material it is perhaps invidious to choose individual items for special mention, more particularly since different readers may be mainly interested in the development of the theory, in the relationship between theory and experiment, or in the experimental technique.

A brief introductory article by Prandtl precedes a long section by Falkenhagen in which are developed the fundamental equations of fluid motion and those special conceptions which are necessary for the comprehension of the subsequent articles. Vortex motion naturally occupies a prominent position, whilst other items of special interest are the theory of Bjerknes' pulsating spheres and the full account of the various attempts to calculate the viscous drag of a sphere, including Goldstein's recent extension of Oseen's solution. Two articles by Tollmien on the boundary layer theory and on turbulent motion give a clear insight into the theories which have been developed from Prandtl's fundamental conceptions, and they provide a valuable review of the position which has been reached in this branch of aerodynamics. The boundary layer theory is now firmly established, and it has the merit that it advances without any empirical aids other than the fundamental conception that the action of viscosity is confined effectively to a narrow layer round a body and to its wake. The theory of turbulent motion, on the other hand, is developed by statistical and semi-empirical methods the validity of which is more open to question, and, although Prandtl's conception of a *Mischungsweg* has led to several interesting and valuable developments, the precise significance of this length is still rather obscure. The theory of the motion of a compressible fluid is also less highly developed, but Busemann gives a clear account of the subject and of the methods of investigating the compression waves which occur when the speed of a body through the fluid exceeds the speed of sound.

The sections dealing with experimental technique explain very thoroughly the measurement of pressure and velocity, and their value is enhanced by the clearness of the illustrations. Remarkable progress has been made in the technique of studying the details of the motion in the narrow confines of the boundary layer, and in the methods of making the flow pattern visible and of recording it photographically. These developments are described in Burgers' article on the hot-wire anemometer, which explains the theory and use of the instrument, and in Tietjens' account of various methods of studying and recording the flow pattern.

(2) This book is of a purely theoretical character and its aim is to develop in a precise form the fundamental theorems of hydrodynamics which constitute the basis of modern theories of fluid motion. M. Villat achieves this object in a clear and concise manner, but it is perhaps to be regretted that he has not found space to include a discussion of Prandtl's theory of the boundary layer. The development of the Kutta-Joukowski theorem, which is the basis of the theory of aerofoils in two dimensions, is perhaps the most interesting feature of the book, owing to the discussion of the singularities which arise when the theorem is applied to a straight line, to the explanation of the paradoxical results derived when the theorem is applied without due care, and to the extension of the theorem to a cylindrical body with isolated point vortices in the surrounding fluid. Other novel features are the proof of Kármán's expression for the drag due to a vortex street and the treatment of the problem of discontinuous flow.

(3) Textbooks of aerodynamics are few in number and generally assume an advanced knowledge of mathematics in the reader. Mr. Whitlock has now written an elementary book which forms a very good introduction to the subject. From the nature of the book it is necessary to accept many results without proof, but the author has succeeded in explaining in a simple manner the theories of the aerofoil and airscrew, the methods of estimating the performance of an aeroplane, and the factors which govern its stability. An occasional looseness of expression may be forgiven, but Mr. Whitlock has fallen into a serious error in introducing the moment coefficient and centre of pressure, owing to uncertainty in his convention of signs. It is regrettable also that he has used an old standard atmosphere, which was replaced by the present international standard some ten years ago.

(4) The fourth book, intended for practical engineers, is of a very different character, and deals mainly with the flow through pipes and the operation of pneumatic tubes. Mr. Eason appears to have read a vast number of original papers and to be acquainted with the latest theories of fluid motion, but he makes no serious attempt to analyse his material critically. A large part of the book consists of a succession of brief notes on the original papers, without any discrimination between experimental results which are old or new, good or bad, fundamental or trivial. The book undoubtedly contains much useful information, but one is left with the feeling that Mr. Eason has devoted too much energy to collecting the material and too little to writing the book.

Applied Entomology.

A History of Entomology. By Prof. E. O. Essig. Pp. vii + 1029. (New York: The Macmillan Co., 1931.) 42*s.* net.

THIS well-produced volume, replete with information and references, is in some ways both unique and exhaustive. Within a compass of rather more than 1000 pages there is related practically everything that is worth recording, and also much that is trivial, respecting the rise and development of applied entomology in the State of California. The point of view of the book is, therefore, essentially western American. The author explains this in the preface, partly on the ground that the historical growth of the subject is much less known in the west than elsewhere in the United States. California has kept well to the fore in applied entomology, and is one of the most highly progressive States of the Union in this respect. This, however, scarcely justifies the disconcerting title borne by the book, and the absence of any sub-title which might proclaim its actual scope.

Prof. E. O. Essig is a leading entomologist in the New World, and the volume before us bears the impress of his characteristic thoroughness and intimate knowledge of his subject. Of the ten chapters into which his book is divided, it will suffice to refer to the more important only. Chap. v., which deals with the injurious insects and mites occurring within the confines of the State in question, amounts almost to a manual on the subject, in its completeness and extensive bibliographies. Chap. vi., which is concerned with biological control, constitutes an authoritative detailed record of the many experiments undertaken in California. This State, it may be added, was the first to apply biological control on a commercial scale. Chap. vii., on insecticides, describes their history and methods of application, and will interest those specially concerned with this branch of insect control. The longest chapter in the book is Chap. ix., "Biography", which runs to just over 270 pages. It includes biographies of most North American leaders in entomology, besides a fair number of Europeans. The latter, however, form rather an odd assortment of names, and their sole connexion with California is often on the strength of having described species that occur within the confines of its territory.

The final chapter (Chap. x.) is a tabular chronological series of dates showing the development and progress of entomology in relation to history and other sciences. Commencing with the birth of Columbus (1446 ?), it carries us finally into the year 1929. A great deal of painstaking research must have been involved in ascertaining and correlating all the dates and events that are recorded. It is, however, often difficult to discriminate in these tables between events and incidents of obviously different values, and many seem to be of rather local interest. In conclusion, it may be said that the scope of this volume embraces much of North American applied entomology. We think that its chief value will be as a reference book, which economic workers will need often to consult, since it is a veritable mine of information difficult to obtain elsewhere. A. D. I.

Short Reviews.

The Poetic Impression of Natural Scenery. By Dr. Vaughan Cornish. Pp. vii + 90 + 4 plates. (London: Sifton Praed and Co., Ltd., 1931.) 6*s.* net.

In this little volume, dedicated to the Earl of Crawford and Balcarres, president of the Council for the Preservation of Rural England, Dr. Vaughan Cornish treats us to a succession of word pictures of homeland and foreign scenes, arranged in three chapters: i. Watching the Seasons; ii. To the Hills; iii. Across the Ocean. There are four beautiful photographs: The Breaking Wave; Bad Weather among the Mountains; The Rushing Torrent; The Placid Lake. The spirit of the book may best be given in the fine words of the author's preface: "The physical features of the landscape are but the warp of the garment of beauty in which the world is clad, the weft is woven by the changing light which sweeps o'er hill and dale. I have watched these varied incidents in many lands, and as the years roll on, the beauty of the Natural Scene makes an ever-deepening impression on my mind, until in later life the transient harmonies of light and landscape are not only the revelation but the image of eternal values."

Here Dr. Vaughan Cornish, a scientific observer, comes prominently to the fore as a poet and nature-mystic, a dual capacity which is happily becoming easier to adopt in these days when the old hard and fast distinctions between the different spheres of reality are tending to break down. At any rate, we strongly recommend the book to all who feel that there is more in a landscape with all its moods and expressions than can be reduced to purely physical terms; to all who if they were told that the difference between the mountains, let us say, when they have withdrawn into themselves asleep in the tranquil haze of fair weather, and the mountains when they are looming forth, glaring at one another in a stormy light, belonged entirely to the 'subjective' realm, would answer with calm assurance that this only begged the question, shifting it further back.

L. C. W. B.

Dixième Conférence de l'Union Internationale de Chimie, Liége, 14-20 septembre 1930. Rapports sur les hydrates de carbone (glucides). Pp. 287. (Paris: Union Internationale de Chimie; London: Hachette and Co.; H. K. Lewis and Co., Ltd.; David Nutt, 1931.) 50 francs; 9*s.*

This publication affords in a convenient form a really valuable collection of eleven papers dealing with various aspects of the chemistry of carbohydrates. These were read at a discussion which took place at Liège, in September 1930, during the tenth conference of the Union Internationale de Chimie. The wide range of the field of chemistry here concerned, its theoretical and technical importance, and the international character of the contribution under notice become evident from a mere glance at the list of contents. The papers deal with the history of monosaccharides (Bertrand), the ring structure of carbohydrates (Haworth), correlations of optical rotatory power and structure (Hudson), mutarotation (Lowry and Smith), starch (Pictet), structure of polysaccharides (Karrer), molecular weight of complex polysaccharides (Pringsheim), X-ray studies of polysaccharides (Mark), the relationship between the properties and applications of cellulose (Heuser), cellulose and its derivatives as colloids (Duclaux), and the relationship of the physical properties of artificial silk to the raw material and the methods of preparation (Viviani).

The publication calls for a cordial welcome, with one qualification: namely, that "the horrible nomenclature of a biochemical committee of the Union"—to quote the justifiable description of Dr. E. F. Armstrong—has been adopted, according to which carbohydrates are called 'glucides', and mono-, di-, and poly-saccharides disguise fair nature under the name of 'holosides'. Fortunately, 'silicides' had already been appropriated!

J. R.

Voice and Personality. By Prof. T. H. Pear. Pp. x + 247. (London: Chapman and Hall, Ltd., 1931.) 10*s.* 6*d.* net.

Prof. Pear has a place of his own among contemporary psychologists. His mind does not work on orthodox academic lines, and his writings are all the more refreshing on that account. Armed with his psychological equipment, he attacks such problems as remembering and forgetting, work and play, and study—topics that appeal to the whole educated public. In the present volume he brings together the results of preliminary research on a subject neglected by the ordinary systematic psychologist. the subject of voices, and of their significance as expressive of personality. Anyone who has had experience of interviewing candidates, or who has tried to analyse the secrets of success on platform or in pulpit, is aware of the subtle effects of voices; and in our time, broadcasting, the sound-film, and the gramophone specially suggest the study of voices.

We do not wonder, therefore, that the subject has occurred to Prof. Pear as an interesting and promising field of research. He would be the last to claim that this piece of pioneer work takes us very far, and he would be the first to insist that, as is usually and properly the case with pioneer efforts, he raises far more problems than he solves. That he has written an interesting book on an elusive subject there can be no doubt.

Gmelins Handbuch der anorganischen Chemie. Achte Auflage. Herausgegeben von der Deutschen Chemischen Gesellschaft. System-Nummer 59: *Eisen.* Teil A, Lieferung 3. Pp. 314-586. 40 gold marks. Teil B, Lieferung 3. Pp. 513-656. 24 gold marks. (Berlin: Verlag Chemie G.m.b.H., 1930.)

The third section of Part A of the volume on iron opens with a discussion of passivity, of which a comprehensive review has been attempted. Then follows the corrosion of iron, chiefly under the influence of aqueous solutions. The compilers apologise for any shortcomings in dealing with corrosion, which they ascribe to a certain lack of co-ordination between the work of different investigators in this field. The latter half of the section deals with the technical production of cast-iron and of wrought-iron. A valuable feature is the inclusion of a list of patent specifications, which will be of great use to those who are engaged in the industry.

The third section of Part B deals particularly with the carbonyls, carbonates, acetates, and derivatives of other organic acids, including the ferro- and ferri-cyanides, the complex cyanides alone occupying 100 pages.

Organic Chemistry for Medical, Intermediate Science and Pharmaceutical Students. By Prof. A. Killen Macbeth. Second edition. Pp. xiv + 296. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1931.) 6*s.* 6*d.*

In its second edition Prof. Macbeth's book has been revised and expanded from 235 to 296 pages, and extra chapters have been inserted on unsaturated hydrocarbons and urea and its derivatives; apart from these changes, the features of the original edition of 1920 have undergone no alteration which calls for comment. In his prefatory remarks the author expresses his opinion that the inclusion of descriptive experimental work in a theoretical text-book is of very doubtful value; many teachers will maintain, however, that the dependence of theory upon experiment cannot be over-emphasised in an exposition of this subject.

The book affords a clear and logical presentation of the fundamentals of organic chemistry which will appeal to the beginner, particularly if he leave for a second reading such topics as the synthetic uses of acetoacetic ester, the ethylene isomerism, space formulæ of sugars, γ-fructose, and the molecular structure of starch.

Annales de l'Institut Henri Poincaré: recueil de conférences et mémoires de calcul des probabilités et physique théorique. Vol. 1, Fasc. 3: *Quelques problèmes de mécanique quantique,* par M. Born; *Quelques propriétés d'une équation aux dérivées partielles hyperbolique,* par Marcel Brillouin; *Sur quelques problèmes non résolus de la physique mathématique classique, Propagation de la fusion,* par Marcel Brillouin. Pp. 205-308. (Paris: Les Presses universitaires de France, 1931.) 35 francs.

The third fascicule of volume one of the *Annales* of the Henri Poincaré Institute is devoted to the lectures given at the Institute by Prof. M. Born and by Prof. M. Brillouin in 1929 and 1930. Prof. Born deals with quantum mechanics, using the matrix method to show, for example, how naturally the statistical interpretation of quantum mechanics may be developed, how it may be applied to the disintegration of the radioactive atom and to the difficult problem of the width of spectral lines, which has recently been dealt with by his pupil Dr. V. Weisskopf. Prof. Brillouin directs attention to the difficulties in the way of solutions of the problems of the motion of a uniform ocean acted on by a periodic force, and of the propagation of solidification within the crust of an otherwise molten earth. Neither problem has yet been solved satisfactorily.

Helgoland und die Zerstörung seiner Felsküste durch das Meer. Von O. Pratje. (Geologische Charakterbilder, herausgegeben von Prof. Dr. K. Andrée, Heft 38.) Pp. 15 + 12 Tafeln. (Berlin: Gebrüder Borntraeger, 1930.) 24 gold marks.

The assurance of geographers that Heligoland is bound to disappear by marine abrasion was used by Lord Salisbury in defence of its retrocession to Germany in exchange for the growing asset of the extending Tana delta. The coastal features of Heligoland are illustrated in this brochure by photographs of the picturesque stacks and natural arches, of the plane of marine denudation, of the undercutting of the cliffs and its acceleration by the effect of organisms, and of the faults in the Triassic rocks. One plate shows views of one place before and after a large rock fall. Each illustration has an explanatory title in English as well as the fuller description in German.

Population and Production.*

By Prof. Edwin Cannan.

The economic history of the last hundred years began with developments which threw great discredit on the fundamental assumption of the old school, that the extension of human occupation of land necessarily meant that less fertile and less well-situated land must be occupied as numbers grew. It was easy for men who saw arable cultivation creeping over barren hills in England and stony 'bogs' in Ireland to believe in that theory when Chicago was a collection of Indian huts and Broadway, New York, a rough cart track to a farm, but the application of steam to ships and railways enabled mankind to extend easily over an immense area of land more fertile than much of what was occupied before. As for situation, not only did the improvement in transport, coupled with the violations of natural geography involved in the cutting of the great ship canals, bring the 'more distant' lands nearer the 'market', but it also eventually brought 'the market' to the 'more distant' lands.

Later in the hundred years, scientific discovery in various directions has led to a complete change of emphasis in regard to the importance of what the old economists used to call 'improvements'. Modern science has changed our outlook. We set no bounds to the possibilities of improvement. We expect to make unwholesome areas healthy, and to modify vegetable as well as animal products so that they will better serve our needs. We smile now at the suggestion made from the presidential chair of the British Association in 1898, that very soon the world would be suffering from a shortage of wheat.

Thus, even if we still expected population to increase very rapidly, we should not believe, as J. S. Mill did, that it "everywhere treads close on the heels of agricultural improvement, and effaces its effects as fast as they are produced" ("Principles", Bk. 4, ch. iii. § 5). But, in fact, Cotter Morison's cry, made only a generation ago, that all would be well if only we could stop for a few years "the devastating torrent of babies" now seems grotesque, for we do not now expect rapid increase of population to continue much longer, even if it becomes progressively easier to obtain subsistence.

The approach of reduction in the rate of growth of population began to show itself in England in the second half of the 1871–80 decade, when the annual number of births became nearly stationary after the rapid increase recorded down to 1876. But the public takes little notice of the supply of people furnished by the births. Just in the wooden way in which illiterate farmers and unbusiness-like old ladies look at their balances at the bank, so the public looks at the censuses. The census of 1881 showed an increase of 14·36 per cent in the decade, which was higher than that shown by any of the censuses except those of 1821 and 1831, which were probably unduly swollen by the diminishing incompleteness of the enumerations. In 1881–91, in spite of high emigration, the rate of increase only dropped to 11·65 per cent, so rapid increase of population was still regarded as the normal thing which everyone should expect.

I had noticed, however, that the old rapid increase in the annual number of births seemed to have come to an end, and, working on the ages of the people as recorded in successive censuses, I put before Section F of the British Association, at its meeting in Ipswich in 1895, a paper (afterwards published in the *Economic Journal* for December in that year) in which I estimated the number of persons who would be living at each census up to that of 1951 on the assumptions that migration, mortality, and—not the rate—but the absolute number of births remained stationary. I found that on these hypotheses the population of England and Wales would stop increasing during the present century, and would have only a trifling increase after 1941.

Hostile critics derided what they called my "prophecy", and for some time events were unfavourable to me. Emigration fell off enormously, mortality decreased, and the births increased slightly, so that the census of 1901 showed an increase of 12·17 per cent in the decade, the absolute increase of three and a half millions being the largest recorded. But the situation was not fundamentally altered, since the increase of births was due entirely to the drop in emigration, which had caused a larger proportion of persons of parental age to remain in the country. In the *Fortnightly Review* of March 1902, I returned to the charge with an article on the "Recent Decline of Natality in Great Britain", in which, using a method of weighting the annual numbers of marriages by their proximity to the births recorded for each year—a method which seems to have been beneath the notice of the mathematical statisticians of that period—I was able to show, I think, conclusively, that the number of children resulting from each marriage was falling steadily and rapidly, and insisted with more emphasis than before on the "considerable probability of the disappearance of the natural increase of population—the excess of births over deaths—in Great Britain within the present century".

The decade 1901–11 was indecisive; the ratio of increase was smaller than in any of its ten predecessors, but the absolute amount of increase just topped that of 1891–1901, and the number of births until 1908 or 1909 seemed to indicate some recovery of natality. But this was illusory. Even before the War the births had got down again to the level of 1876. The War sent them tumbling down to about three-quarters of that number, and now, after a wild but very short-lived recovery when the Army returned from abroad, they seem inclined to settle at the War figure—three-quarters of the number attained more than fifty years ago, when the total population was twenty-six millions instead of forty millions, as it is now. The ratio of births, legitimate and illegitimate, to my weighted figure of marriages which was just over 4½ fifty years ago, fell gradually and steadily to 3¼ before the War caused it to collapse.

---

* From the presidential address, entitled "The Changed Outlook in Regard to Population, 1831–1931", to Section F (Economic Science and Statistics) of the British Association, delivered in London on Sept. 25.

Diminution of infant mortality mitigates the effect of decline of natality, but the degree in which it can do so obviously decreases as the rate of infant mortality falls. When that rate is 500 per thousand, as it probably was in England in the reign of Queen Anne, and may be still in great parts of Africa, a cutting down of births by 25 per cent can be counteracted completely by a drop of one-third in the infantile mortality rate. But when the infant mortality rate is down to 100 per thousand, it would have to fall to nothing at all in order to counteract a decline of only 10 per cent in the number of births. In fact, the rate has fallen in England and Wales from about 140 to about 70 in the fifty years from 1881, and this drop to one-half only balances about one-fifth of the decline in the number of births.

Though there were eminent dissentients only a few years ago, statisticians are now agreed that, in the absence of some great and unexpected change, the increase of population in England and Wales will come to an end at a very early date. Even the lay public has been to some extent enlightened and rather shocked by the recent census announcements that the population of Scotland has actually decreased in the ten years, and that of England and Wales has increased only 2,061,000, as against 3,543,000 in the ten years from 1901 to 1911, though the emigrants have been 324,000 less.

The same change is observable in some degree in other western European countries and our own oversea offshoots. The cause of it—birth control—will doubtless in time affect the rest of the world, so that while we may expect considerable increase—even an increase much more rapid than at present owing to decrease of huge infant mortality—to take place among the more backward peoples for another half-century at least, there is no reason whatever for expecting the population of the world to " tread close on the heels of subsistence " in the future, even if it may be correctly regarded as having done so in the past.

This change in our expectations involves many changes of emphasis, both in the theory of production and in that of distribution. Two of them are perfectly obvious. First, the need, which J. S. Mill and most of his contemporaries and immediate predecessors felt so strongly, for insisting on the due restriction of population, has completely disappeared in the western countries. Economists do not now require to talk as if the first duty of men and women is to refrain from propagating their race. Secondly, the need for insisting on the desirability of saving has become less pressing. A rapidly increasing population requires a rapidly increasing number of tools, machines, ships, houses, and other articles of material equipment in order merely to maintain without improving its economic condition, while at the same time the maintenance of a larger proportion of children renders it more difficult to make the required additions.

There are, however, other changes of equal importance which are more likely to be overlooked. One is in regard to the weight which we attach to the different kinds of production. In the middle of the eighteenth century ' subsistence '—and what we should consider a very coarse and inadequate subsistence—probably seriously deficient in vitamins, appeared so much the most important economic good that the French *économistes* insisted on calling all labour which did not get something out of the soil *stérile* or barren ; and our own Adam Smith, with all his common sense, while admitting the manufacturing class into the ranks of ' productive ' labourers, insisted on excluding domestic servants, physicians, guardians of law and order, and all other workers who did not make up material objects, or who were not employed for profit (he never was quite sure which criterion he meant to stand by). The great Christian philosopher, Paley, believed that nothing more than a " healthy subsistence " was required for perfect happiness.

All this emphasis on food is now out of date. We no longer look forward to a future in which an increasing population will be forced by the operation of the law of diminishing returns to devote a larger and ever larger proportion of its whole labour force to the production of food. We know that even in the past, with a rapidly increasing population, the returns to agricultural industry have increased so much that civilised mankind has been able to feed itself better and better, while giving a smaller and ever smaller proportion of its whole labour force to the production of bare subsistence ; and we can reasonably expect that the increase in the productiveness of agricultural industry will be at least as great in the future, so that under the combined influence of the " narrow capacity of the individual human stomach " and the stationary number of stomachs, not only a smaller and ever smaller proportion but also a smaller and smaller absolute number of workers will be able to raise food for the whole.

Even the politicians, who for the most part follow the economists with a sixty or seventy years' lag, are beginning to realise the change, and are losing their enthusiasm for schemes for " settling more people on the land ", either in colonies or at home, and thereby increasing the already excessive depreciation of agricultural compared with manufactured products. The numerous subsidies which they still give to agriculture are mostly of an eleemosynary character intended to relieve distress, and the encouragement which they give to agricultural production is only an incidental effect, unintended and often deplored. They are defended, not on the ground that they increase food, but because they are supposed to increase employment.

The necessary change of emphasis applies not only as between food and other things, but also as between most primary and most finishing industries. In face of rapidly growing knowledge and slowly growing or stationary population, it is inevitable that the ' staple ' or ' heavy ' industries which provide materials should decline relatively to those which provide finished goods and services. The demand for each of such things as pig-iron and yards of cloth is easily satiated; and so also is the demand for cricket-bats and chauffeurs. But the minor or 'lighter' industries are susceptible of an indefinite multiplication which makes the demand for their products, taken as a whole, insatiable. Increase a person's power of spending, and he will not increase his purchases in weight or bulk so much as in refinement of form, so that a richer people will devote a less proportion of their labour to producing things like pig-iron and bricks. Moreover, the mere fact of the disappearance of rapid increase of population tends to increase the proportion of demand which can be satisfied from scrap without fresh primary production. So, given a stationary population with rapidly increasing knowledge applied to production, we may expect the already observable tendency towards a less proportion of the whole labour-force being employed in the 'heavy industries' and a larger in the lighter industries to become more pronounced. Perhaps we see this even now in the slight drift of industrial population from the north to the south of England which appears to be taking place.

Another change of emphasis, of little importance on the Continent, where the West-Ricardian theory of rent never took real root, but of great importance in England and other English-speaking areas, is in respect of the landowners' share of the community's income. The disappearing bugbear of diminishing returns carries away with it the vampire rural landlord, who was supposed to prosper exceedingly when diminution of returns made food scarce and dear. The famous passage in which J. S. Mill described the landlords as they appeared to him and the school which he, a little belatedly, represented is well known:

"The ordinary progress of a society which increases in wealth is at all times tending to augment the incomes of landlords; to give them both a greater amount and a greater proportion of the wealth of the community, independently of any trouble or outlay incurred by themselves. They grow richer, as it were, in their sleep, without working, risking, or economising" ("Principles", Bk. 5, ch. ii. § 5).

Perhaps the disciple went a little beyond his master, Ricardo, in asserting so roundly that in a prosperous society the landlords must tend to get a larger and ever larger *proportion* of the whole income, but there can be no doubt that this was the impression which the Ricardian school conveyed to the public, and which formed the foundation for Henry George's scheme of land nationalisation and the agitation for land-value taxation. If the school had only meant to teach that the land became more valuable absolutely—in the sense of being worth a larger absolute amount of commodities rather than a larger proportion of all the commodities and services constituting the community's income—they could not have supposed land so peculiar, since it would share this characteristic with many other things—with anything which was more limited in supply than the generality.

To grasp the completeness of the change of view which has taken place in the last hundred years, we must notice that Mill and the whole school which he represented were thinking not of the few lucky landlords who have inherited land which has been selected by Nature or accident as the site of a city, but of the ordinary rural agricultural landlords. So far have we moved that the land-value taxers of to-day quite cheerfully propose to exempt all 'purely agricultural value' from the imposition which they advocate.

Envy of the happy owners of such urban land as rises in value more than enough to recoup what they and their predecessors in title paid in road making, sewering, and other expenses of 'development' plus loss, if any, in waiting for income, still plays a part in contemporary politics, but the economist foresees that there will be at any rate less of such rise of value when the adult population ceases to increase and the demand for additional houses and gardens consequently disappears. He realises that if any such rise continues, it will be due to the people being not only able, as they doubtless will be, to occupy a larger area with their houses and gardens, but also desirous of doing so. He will think this quite possible, but will not be confident about it, when he reflects that the vast spread of 'villadom' may be only a temporary phenomenon, and that the married couples of the future, childless or with small families, may be more content with flats in towns and little bungalows with tiny curtilages right in the country.

The disappearance from economic theory of the picture of the vampire landlord taking an ever-increasing proportion of the whole produce of industry, which was itself decreasing per head of workers, leaves the theoretical arena open for discussion of the sharing of the whole produce between earnings of work and income derived from possession of property of all kinds.

As to this, the economists of a hundred years ago had nothing to say. The socialists, who followed them in fact the more closely the more they denounced them, failed completely to clear up the confusion, and it dominates the mind of the lay public even now—much, I admit, to the discredit of the economists, who should have taught that public better.

While there are no statistics on the subject worth much, and none covering any considerable area either of place or time, past history is sufficiently known to assure us that increasing civilisation has, in fact, made the aggregate share of property grow faster than that of labour, the obvious cause of this being that useful things constituting property have grown faster than population, and so much faster that what decline of the rate of interest has taken place has not been sufficient to counteract the tendency.

There is nothing to show that this tendency will be either reversed or intensified by a cessation of the growth of population. The cessation will, of course, tend to reduce the desirability of additional equipment; a large part of the additions of the past have been required simply to enable the additional people to be provided with tools, houses, and other instruments of production or enjoyment. But additions to equipment will be made with less sacrifice of immediate enjoyable income than before, so that the increase of quantity may be sufficient to counteract the decline in the value of the units. Moreover, it is quite impossible to say what the tendency of invention may be in the future—whether to enhance or to diminish the value of additional material equipment.

The history of the last hundred years suggests that this question of the division of income between property and labour is losing whatever importance it possessed. The economists and socialists of a hundred years ago were little removed from the time when it was common to talk of ‘ the labouring poor ’, as if society was fairly sharply divided into poor workers on one side and rich owners of property on the other. How innocent the mass of the people were of the crime of owning anything may be realised if we recall that none of the agencies with which we are familiar for enabling them to invest had then got beyond the embryo stage. Friendly societies, co-operative societies, building societies, savings banks, are all modern growths.

The present position is that, while many of the working-class have become property owners, many of the propertied class have become the paid servants of public companies and other institutions. Hence the old sharp distinction between the wage-earner and the capitalist is become a thing of the past, and the division of income between property and labour is no longer a division between two classes composed of different individuals, but a division between two sources of income largely possessed by the same individuals.

Thus, in distribution, emphasis on the old categories of land, capital, and labour is rapidly becoming obsolete and is being replaced by emphasis on individual riches and poverty, however arising. It is no longer the lowness of standard earnings that worries the philanthropic economist, but the fact that so many people are unable to rank themselves among recipients of those wages. Emphasis is on unemployment.

Unemployment is not really a very modern phenomenon. But, so far as I know, it has never been contended that history shows unemployment to be greater when population (or even population of working age) is rapidly increasing. Yet it is common to talk of ‘ the difficulty of providing employment for a rapidly increasing population ’, and some eminent authorities quite recently endeavoured to console the public by alleging that the coming decline in the growth of numbers will greatly alleviate the present situation in regard to unemployment.

I believe this to be a profound error, based on an elementary misconception of the origin of demand. The old proverb “ With every mouth God sends a pair of hands ” is true and valuable, but no more so than its converse, “ With every pair of hands God sends a mouth ”. The demand for the products of industry is not something outside and independent of the amount of products. The demand for each product depends on the supply of products offered in exchange for it, and the demand for all products depends on the supply of all products. Consequently, there is not the slightest danger of the working population ever becoming too great for the demand for its products taken as a whole.

Unemployment arises not from insufficient demand for the products of industry as a whole, but from the number of persons offering to work in particular branches of industry being in excess of the number admissible, having regard to the conditions and wages which are required to satisfy both the would-be workers who are unemployed and the persons already in employment. If the unemployed will not take what employers would offer them, the case is simple, and it is only a little more complicated if they are willing to take, and the employers are willing to give, something less than what is paid to the persons already employed.

Now one of the commonest causes of such a situation is a falling off of demand for the products of a particular branch of industry. The fact that the demand for any product, let us say coal, for example, falls off, is a good reason for fewer persons being employed in that branch of industry and more in other branches. If the diminution of demand is very gradual, the necessary reduction in personnel can be effected by a cessation of recruiting. Many a branch of industry has gradually wilted away in this manner without much inconvenience or hardship to anyone. But if the diminution is more sudden, unemployment results owing to the natural reluctance of persons skilled, or at any rate experienced, in the particular branch of industry to leave it and try for employment in some other.

The thoughtless outsider is apt to say that both the unemployed and those who are still employed in the branch should accept lower wages, and so, by cheapening the product, extend the demand for it. As a temporary palliative this may sometimes be reasonable, but it is evidently never the best final solution of the difficulty. It is not reasonable that a trade should be continuously worse paid than others merely because the demand for its products was once bigger than it has become. What the diminution of demand calls for is a redistribution of labour force, fewer persons being allotted to the branch of industry of which the products are less in demand, and more persons to the other branches.

When population is increasing, absolute diminutions of demand are likely to be somewhat fewer, and somewhat less acute when they do occur, than when population is stationary. If, for example, by the introduction of oil, or more economical consumption, the average person's demand for coal is reduced by one-tenth, in a stationary population the total demand for coal would be reduced by one-tenth ; but if the population in the same time increased 12 per cent, the total demand would be not reduced but slightly increased, and there would be no employment difficulty.

We ought, therefore, not to imagine that a stationary or declining population will rid us of the trouble of unemployment. It will provide more rather than less reason for promoting mobility of labour in place and occupation.

The Recorded Data of Science.

A FAVOURITE simile likens the growth of modern science to the rise of a great edifice which, in its different parts, presents to the world a variously incomplete appearance. The broad foundations have long since been laid, and immense pillars already stand erect upon them, whilst there are sites where excavation has not yet laid bare unyielding rock, and places where surveyors have condemned an unsound structure. It is an inspiring picture, but the architects and the masons need something more than inspiration. Their work cannot be based on impressions; it requires plans, records, specifications, quantities, and the clerks and draughtsmen in an obscure office contribute in full measure to the success of the enterprise. The picture is incomplete unless it exposes the weakness of what appears to be strong and discloses the content of what might be taken for hollow space; moreover, if it has regard for truth, it must give due prominence to the dust of time which lies heavily on the joints and conceals their true relation to the frame. Only the written records reveal the exact condition and the manner of construction of the building, and the written record affords, after all, the essential preparation for every scientific expedition.

Knowledge cannot safely move forward without first retracing its steps and surveying its path; the searcher cannot safely plunge into the unknown until he has acquainted himself with the known. We are not for the moment concerned with the adequacy or otherwise of that acquaintance, although a survey of scientific journals would quickly provide material for discussion; we have in mind the bibliography of the literature of science, the service of abstraction and compilation, and the great importance of accessibility, as well as preservation, of scientific records. It is not sufficient to commit results to paper; it is not sufficient to publish them in a widely read journal, even in a widely understood language. When the journal has been placed on a shelf beside its fellows, and a more recent issue takes its place on the desk, it is the turn of bibliographers, abstractors, and indexers to make their essential, if unpretentious, contribution. The work has to be performed without intermission, and it should be entrusted to those who are able to combine an appreciation of the significance of the subject matter with experience in the art of its treatment.

This desideratum applies not only to the preparation of standard publications of reference, but also to that of reports for the use of individuals and of scientific and industrial corporations. If the results attained by former investigators are to be of service in future research, they must be sought, identified, collected, and preserved, and this is a task of great and increasing magnitude. It is satisfactory, however, that the wider need for expert assembly and use of such records is being realised, and that the growth of libraries is being accompanied by the establishment of a branch of the profession of librarianship trained and exercised in the functions of special libraries and information bureaux. The efficiency of such organisations, and the solution of their special problems, cannot fail to be influenced by the establishment of appropriate facilities for training and practice; neither can it be denied that scientific research and industrial progress must inevitably reap the advantage.

We have been led to discuss special librarianship by our reflections on the position of scientific literature as a tool in research, reflections which originated from our having occasion to refer to the "Annual Tables of Constants and Numerical Data for Chemistry, Physics, Biology, and Technology", a publication based on work which has been in progress internationally for twenty years. The origin and history of the enterprise, which is at the same time an outstanding addition to the literature of science and a demonstration of international co-operation in the cause of science, were fully explained by the secretary-general, M. C. Marie, in a lecture delivered in 1928 before the Swiss Chemical and Physical Societies. Dr. Marie then pointed out how much important numerical information is buried in papers the titles of which gave no indication of its presence, and hence is easily overlooked. On his report to the seventh International Congress of Pure and Applied Chemistry held in London in 1909, a commission was appointed and immediately commenced its labours. At first the literature was examined by a large number of collaborators, but this method proved inexpedient, so that since 1912 a different procedure has been employed. There is now appointed in each important country at least one representative, who prepares slips referring to numerical data and forwards them quarterly, together with parts of the relevant literature of that country, to the editors who (with the assistance of experts in each subject class) are responsible for the extraction of the data; hence the inhomogeneity of the earlier volumes is largely avoided.

The publication was at first confined to the data of physical chemistry, but it soon became obvious that its scope must be extended to include pure and applied sciences specified in the title, which still does not refer to important sections such as mineralogy and crystallography. Only data concerning substances or definite systems are recorded, data lacking adequate precision being referred to only in the bibliographies; for it is useless to record figures which have no significance. Obviously, there can be no invariable rule, and the limits must be fixed by experience, but with this provision the aim is "to publish everything in the physical and natural sciences and their applications that can be represented by numbers". Apparent inhomogeneity due to the coexistence of two forms of classification—according to the nature of the constant, and according to the nature of the substance—is retained in order that information of particular interest to groups of specialists may be presented in a convenient form. Thus the properties of rubber are conveniently found in the same part of the engineering section, and not dispersed among the chapters on density, viscosity, etc. As befitted an international work published in Paris (Gauthier-Villars et Cie), the tables were originally printed in French, although certain introductory pages bore translations in English, German, and Italian. Commencing with volume 7, however, the international character of the work has been emphasised by the presentation of the complete text in both English and French, whereby its sphere of usefulness will naturally be extended.

The convenience not only of English-speaking peoples, but also of specialist groups, has been considered. To an increasingly great extent, workers in particular branches of the tree of knowledge require special assemblies of numerical data to facilitate their researches and to save them wearisome hours in sifting their particular needs from those of their colleagues. This demand has been supplied by the publication of separate sections on spectroscopy, electricity, magnetism, electrochemistry, mineralogy, crystallography, etc., the possession of which may in many cases render superfluous that of the complete volumes.

Research workers themselves require no admonition to secure access to works of reference such as the "Annual Tables", which derive their value not only from their contents, but also from their lacunæ. These gaps may be due to commission or omission. As Dr. Marie points out, inadequate specification of the conditions of measurement may render the results of that measurement completely worthless; moreover, it is only when scientific information concerning the properties of matter is arranged in an orderly manner that missing and weak links in the chain can be quickly detected. Hence the work of compilation of a complete record, when carefully performed, must to a certain extent stimulate criticism, and must therefore lead directly to advances in our knowledge concerning the material criticised. So also the record itself is a source from which critical tables may be, and have been, derived. Dr. Marie refers to the snare of those values which merely masquerade with an air of 'precision', but he is careful to insist that incompatibility must never be condemned unexamined, and cites as a cogent example the unsuspected reason for such incompatibility in determinations of the density of nitrogen. On the other hand, the "Tables" are not selective, although the service rendered by similar selective compilations is not overlooked by their editor, who, however, aims at catholicity.

The first three volumes surveyed the data published during 1910, 1911, and 1912, but the early progress of the undertaking was soon to be interrupted by the outbreak of the War, and inevitable delay resulted; nevertheless, by 1922 the fourth volume (1913–1916) was published, and was followed in 1925 by the fifth (1917–1922), in 1928 by the sixth (1923–1924), and in 1930 by the seventh (1925–1926) volumes; the first part of volume 8 (1927–1928) and volume 9 (1929) are due to appear in 1931, and the second part of volume 8 early in 1932. In February last the work was enriched by the publication of a collective index to the first series (vols. 1-5), and a similar index to the second series is announced for 1933. The index is tripartite, comprising an analytical, an alphabetical, and a formula index; with its aid numerical data published between 1910 and 1922 for more than 20,000 substances can be readily traced under the French name; whenever necessary, English, German, and Italian names are also given. Thus recovery from the War and its aftermath is all but complete, and the delay in the accessibility of the data will soon be no greater than the natural hysteresis between original and collective publication. Even such delay as is now imposed can be circumvented, for the editorial organisation necessarily constitutes a bureau of information, to which individual application for assembled but unpublished information may be made.

In his lecture, Dr. Marie gave some account of the financial basis of this international enterprise. An early conviction that independence of commercial interests was essential led to the refusal of an attractive proposal made by a German publisher; of the subscriptions received at this period, specially honourable mention is made of two: a modest sum from a society of students in Uppsala and a substantial donation from the Imperial Academy of Sciences of Vienna, the good example of which was followed by other scientific bodies. In 1918, with the view of the publication of the fourth volume, a French fund was established; in 1922 the financial basis was broadened by the creation, at the instance of the Union Internationale de la Chimie pure et appliquée, of an international scheme providing for subvention in relation to population. So far as is possible, the government of each respective country sponsors the subscription; the British contribution is provided by the Royal Society. In this way sums sufficient to permit the publication of vol. 5 were gradually collected, whilst the preparation of certain subsequent volumes was facilitated by subventions from the International Education Board and from French industrial organisations; in 1928 Dr. Marie was able to announce that the financial undertakings given by various countries would, so far as could be seen, permit the "liquidation of the past".

It would be ungrateful to describe the work and the organisation in so nearly impersonal terms; Dr. Marie's present collaborators—E. Cohen (Utrecht), P. Dutoit (Lausanne), A. Egerton (Oxford), O. Scarpa (Milan), F. K. Richtmyer (Ithaca), and C. J. West (Washington)—deserve the thanks of the scientific community, which will remember also with equal appreciation the names of Abegg, Bodenstein, Bruni, Stieglitz, Washburn, and Wilsmore in connexion with the creation of what is equally a worthy example of international work and a work of international worth.

Cancer Research.*

THE British Empire Cancer Campaign continues to subsidise a great variety of investigations into the cause and treatment of cancer, and the progress which is being made is summarised fairly fully in the recent annual report.

The greatest practical advance in the cancer problem which has been made in recent years is the cumulative demonstration that tar and soot and, generally, the products of burned coal, together with certain mineral oils, have an exceptional efficiency in causing malignant tumours when they are applied to the tissues of men and animals over long periods of time. The evidence comes partly from experiments on animals and partly from studying the relation of cancer to occupation and mode of life. The two lines of inquiry are entirely concordant in implicating burnt coal, and they provide sanitarians with a clear indication for preventing some forms of cancer.

For experimental purposes tar has generally been used as a carcinogenic agent, and a good deal of research has gone into the obvious question as to what particular substance in that complicated mixture is responsible. Most of the components have been tried and found to be inert, and no pure substance has been found which had anything like the effect of tar. It seems now, however, that Mr. I. Hieger and Dr. J. W. Cook, at the Fulham Cancer Hospital, have made substantial progress by following up the observation that benzanthracene and cancer-producing tar have similar fluorescent spectra. They have since found that 1 : 2 : 5 : 6-dibenzanthracene in a high state of chemical purity readily produces cancer when applied in quite small concentrations to the skin of mice, and they have thus provided a most valuable method for the analysis of the precise mechanism by which such cancers are produced. Whether this or some analogous compound is in fact the active agent in tars and mineral oils is not known.

There is at any rate no obvious justification for the statement made in the Report of the Grand Council (though not, we notice, by the workers themselves) that " the essential molecular structure of the cancer-producing agent in tar and other cancer-producing substances " has been determined. It may well be that the agent is not the same in all tars and carcinogenic oils. Cancer of the skin may be produced experimentally by X-rays, freezing, burning, acids, and other procedures which irritate the skin and have no 'substance' in common, though they may be similarly active because they all lead to the tissues producing the same active agent.

Another inquiry which relates the chemical constitution of a substance to its capacity to cause the growth of cells has been carried out by Dr. J. S. Young at Leeds. Solutions of simple salts injected into the pleural sac stimulate the cells lining the marginal alveoli of the lung to proliferate, and their efficiency in a general way varies with the valency of the metal: aluminium is more effective than calcium, and calcium than sodium. To these interesting facts he has now added the observation that cells which have reacted once are refractory to a further application of the stimulating salt for about three weeks. This resistance may also be induced by a series of injections of gradually increasing strength such that no reaction is at any time produced: ultimately the cells tolerate a concentration of the salt twice as great as that required to cause a reaction in a normal animal. This kind of cellular immunity to irritating substances is little understood and needs further investigation, possibly on simpler material than that used by Dr. Young.

While these and other data indicate quite clearly that cancer is essentially a local disease due to local causes, it is also evident that general or constitutional factors may be involved. In the present report, for example, it is shown that some strains of mice respond more quickly to the application of tar than others, and mention is made of a breed in which tumours appear 'spontaneously' in an extraordinarily large percentage of animals. Dr. C. E. Dukes also presents the pedigrees of a number of human families in which a hereditary predisposition to the development of multiple innocent tumours of the bowel is plainly shown: in many cases these growths form the starting point of cancers which appear at an exceptionally early age. It may probably be presumed that by deliberate dysgenic mating, strains of men might be produced with a special tendency to respond to external irritants by the growth of cancers, but there is no evidence that the constitutional factor is of any substantial importance in an ordinary human society, except in a few special instances such as that studied by Dr. Dukes.

---

* British Empire Cancer Campaign, Eighth Annual Report of the Grand Council, presented at the meeting held at the House of Lords on July 20. (London: British Empire Cancer Campaign.)

Obituary.

DR. JOAN B. PROCTER.

SELDOM has the triumph of force of mind over physical weakness been more vividly illustrated than in the case of Dr. Joan Beauchamp Procter, curator of reptiles and amphibians in the Gardens of the Zoological Society of London, who died at her residence in Regent's Park on Sept. 20, at the age of thirty-four years. Fragile from birth, she still persisted in her duties, first at the Natural History Museum and later at the Zoo, when the majority in like position would excusably have retired.

From quite early days she had dedicated her abilities to the subject which was to become her life's work. As a child she showed an extraordinary interest in reptile and amphibian life, snakes, lizards, and frogs taking the place of diversions more usually associated with the nursery—and often causing consternation and alarm amongst her relatives and visitors. Whilst still at St. Paul's Girls' School, she called upon my father, Dr. G. A. Boulenger, F.R.S., who at that time was in charge of the reptile and amphibian collections at the British Museum. He at once perceived in her the makings of a brilliant herpetologist, and when she left school he invited her to work under his direction. Her special capabilities found full vent, and so valuable was her assistance that when my father retired, in 1920, Miss Procter was given the management of the vast collection. She proved not only an admirable systematist, but also an accomplished draughtswoman and modeller, and was responsible for some of the showcases in the Reptile Gallery in the Natural History Museum, and for a large series of coloured postcards of reptiles on sale at the Museum.

In 1923, Sir Peter Chalmers Mitchell, secretary of the Zoological Society, asked her to assist me in the design of the rockwork of the new Aquarium, then in course of construction, and later invited her to take over the curatorship of the Reptile House—the Aquarium at the time monopolising all my attention. As curator of reptiles she was an unqualified success, her great knowledge of reptiles coupled with her remarkable manual dexterity enabling her to perform many surgical operations on her charges that had not hitherto been attempted. The new Reptile House, opened in 1927, may fairly be regarded as a lasting monument to Miss Procter and her work. It combines the most modern developments of heating, lighting, and general hygiene, all of which she was quick to appreciate. The house, moreover, blends scientific requirements with artistic embellishment in a manner that had not hitherto been attempted in any zoological collection. During her curatorship at the Zoo she turned her artistic abilities to full account, and the majority of the more modern buildings and enclosures in the Regent's Park menagerie bear her stamp. The Reptile House, however, is preeminently her achievement and a worthy climax to an all too brief career.

Amongst her many contributions to scientific literature, her monograph on that remarkable tortoise *Testudo loveridgei*, published in the *Proceedings of the Zoological Society* in 1922, may be specially mentioned.

Miss Procter will be mourned by all those who were privileged to come into personal contact with her. A larger number outside her immediate circle will miss an artist and a valuable contributor to knowledge—one who did so much and in so brief a period. E. G. Boulenger.

Sir Gregory Foster, Bt.

Sir Gregory Foster, whose death occurred on Sept. 24, at the age of sixty-five years, was a singularly able and devoted worker in the cause of education and of university education in particular. He entered University College, London, as a student in the 'eighties, graduating in 1888. He studied afterwards under ten Brink at Strasbourg, obtaining the degree of Ph.D. He was for some time professor of English at Bedford College, which was then situated in Baker Street, London, and he returned to University College as secretary and lecturer, becoming principal (afterwards provost) of the College in 1900, and holding that appointment until his retirement in 1929. In 1928 he was elected vice-chancellor of the University of London and was re-elected to that office in 1929. The greater part of his life was therefore spent in connexion with University College and the University of London.

The period during which Foster was provost of University College was one of the most notable in its history. The status of the College was altered by its incorporation in the University in 1907. Under his guidance its position was extended and consolidated in a remarkable degree. Existing departments were strengthened and new departments created, new chairs were established, and many additions of great importance were made to the curricula. The School of Librarianship and the Department of Scandinavian Languages owe much to him. The magnificent range of laboratories in connexion with the Department of Chemistry, the great buildings devoted to the medical sciences, and the Architectural and Engineering Departments are among the most important university buildings erected in England in recent years. Foster would have been the last to claim that he was primarily responsible for this remarkable growth in the equipment and resources of the College, for he preferred to give the credit to others. The College is not likely, however, when honouring his memory, to forget the part he played or the great gifts of leadership which he displayed.

Foster was devoted to the interests of the students, and he carried on and developed the work begun by Henry Morley, for whom he had a great admiration, in fostering a corporate life in the College. He was a strict disciplinarian, but his innate kindness brought instant and unobtrusive help to many, of all nationalities, who were in difficulty. Thus, in spite of the reserve which gave him his dignity of bearing, he won the popularity which comes to fearless and humane men who do not seek it. He gave himself without stint to the College, and its welfare and advancement were ever in his thoughts. He never spared himself. Possibly he worked too hard, for he was unwilling to delegate to others any duty that he thought important, and in the opinion of his friends he would have been wise to have 'let go' when, a few years ago, his health showed serious signs of strain. He never lost his early interest in philological studies, in which he doubtless would have made his mark had not other duties engrossed his attention.

Although primarily concerned with University College, Foster was interested in many educational questions generally. He was always a staunch friend to the cause of women's education, and when he became vice-chancellor of the University of

London he was concerned with the facilities offered to medical women and generally with improving residential and social facilities for London students. Until quite recently, as chairman of the Council, he was endeavouring to raise funds for College Hall for Women in Bloomsbury. He had always been a prominent advocate of reform in the constitution of the University, of which he was a devoted son, and the University was fortunate in that at the difficult period of transition from the old statutes to the new he was, in the position of vice-chancellor, able to bring about the necessary changes with the least possible friction.

His health had not been good for some little time, but he endured the pain and inconvenience of illness with fortitude and fine courage. He will be greatly missed and not soon forgotten. E. D.

MR. J. W. TAYLOR, of Leeds, who died on Sept. 2, in his eighty-seventh year, was the doyen of British conchologists and was responsible, more than anyone else, for the intensive study of our land and freshwater Mollusca. He founded the *Journal of Conchology* in 1874, and with some of his friends (of whom Mr. H. Crowther still survives) established the Conchological Society in 1876. In 1894 he began the publication of his "Monograph of the Land and Fresh-water Mollusca of the British Isles", probably the most complete account of any group of animals which has been attempted, and beautifully illustrated by himself. The second volume, written in conjunction with W. D. Roebuck, is the only satisfactory description of British slugs. Unfortunately, with less than half completed, publication has been suspended since 1921. Mr. Taylor was a printer, and received the degree of M.Sc. from the University of Leeds in 1915.

WE regret to announce the following deaths:

Dr. Francis Barnard, honorary curator of coins and medals in the University of Oxford and formerly professor of medieval archæology in the University of Liverpool, on Oct. 9, aged seventy-six years.

Prof. C. L. Bristol, emeritus professor of biology in the University of New York, known for his researches on the marine fauna of Bermuda, on Aug. 27, aged seventy-two years.

Sir Arthur E. Cowley, fellow of Magdalen College, Oxford, and late Bodley's librarian, on Oct. 12, aged sixty-nine years.

Prof. J. B. Goesse, *S.J.*, emeritus professor of geophysical observations in the Saint Louis University and founder of the geophysical observatory of the University, on July 25, aged sixty-two years.

Prof. J. Long, formerly professor of dairy farming at the Royal Agricultural College, Cirencester, a well-known agricultural writer, on Oct. 1, aged eighty-five years.

Prof. Richard A. F. Penrose, jr., formerly professor of geology in the University of Chicago, and formerly a member of several State geological surveys and also of the U.S. Geological Survey, on July 31, aged sixty-eight years.

Prof. James T. Porter, head of the Department of Physics in the University of Tennessee, on Aug. 27, aged fifty-seven years.

News and Views.

IT was widely believed in the seventeenth century, even by Otto von Guericke for example, that air could be condensed into a watery liquid by compression. The origin of this belief is discussed in a note by Prof. E. O. von Lippmann in the *Chemiker Zeitung* for Sept. 5. He points out that the transformation of air into water is implied in early Greek philosophy and in Aristotle's theory of the elements, but he thinks the transmission of the belief is to be ascribed to Lucian (second century A.D.), who, in his satirical "True History", relates how a ship was blown by a whirlwind on to a star, from which the shipwrecked travellers saw the earth below as a shining sphere. The inhabitants of this star took as food only the vapours of flying frogs roasted over fires, and as drink, air condensed to a liquid in vessels by pressure. Lucian, who is generally supposed to have no claim to originality, may have derived the idea from some unknown earlier writer. In amplification of Prof. Lippmann's interesting note, it may be added that the writings of Lucian (available in an excellent English translation by H. W. and F. G. Fowler: Oxford, 1905) contain many such hints, concealed by the very artificial style of the author. Lucian refers, for example, in the same "True History", to a peace treaty between the inhabitants of the sun and moon, engraved on a tablet of electrum and set up on the frontier between their territories. This undoubtedly refers to the use of electrum, as an alloy of gold and silver, as a kind of neutral material combining the properties of both gold and silver, which are associated with the sun and moon respectively. Electrum, however, is referred by contemporary and later neo-Platonic writers to a separate planet, Jupiter or Mars, and the date of its removal from the list of planetary metals and replacement by the metal mercury has been discussed (for example, by Berthelot) without mention of Lucian's hint. There are several other similar references made by this author which are of interest in the history of science.

DR. H. MARTIN LEAKE, in the *Contemporary Review* for September, voices a plea for the establishment of biology on the basis of a real profession. Of late years there has arisen a widespread demand for trained biologists, due to the post-War development of the Colonies, which lie mainly in the tropics. The demand exceeds the supply, and this is not adequately explained by lack of educational facilities. The basal trouble appears to be the lack of that security of tenure and emolument which is essential if workers of the right calibre are to be attracted to biological study. At present the biologist has such a restricted and specialised market for his services that security is attained only under the wing of other professions. His work is chiefly needed in connexion with agriculture, which is beginning to substitute a firm scientific foundation for the empiricism which has hitherto been the guiding principle for the majority of those practising agriculture as a profession.

As Dr. Martin Leake remarks, the upsetting of the balance of Nature in colonial development has raised a multiplicity of field problems needing investigation by trained research workers, and under present conditions it is only the Government which is in a position to provide the necessary funds, which will thus entail a single employer, the Colonial Office. A few other interests, especially tea and rubber, have begun to employ biologists, but so far the demand from such quarters is too small to affect the professional question. Dr. Leake indicates the need for a link between research and practice, the fact that the generalisations of research frequently need interpretation with local requirements, and that the research organisation does not replace, but complements, the technical staff within the commercial unit. Such a development, if it took place on a scale materially to affect the system of agricultural production in the tropical Empire, would do much to improve the status of biology as a profession, would increase the demand for trained biologists, would provide security and adequate remuneration, and would remove the dangers inherent in the concentration of demand for services in the hands of a single employer.

AT the opening of the School of Pharmacy of the Pharmaceutical Society, which is also the School of Pharmacy of the University of London, on Oct. 7, an address to the students was delivered by Prof. G. E. Gask, of St. Bartholomew's Hospital Medical School and dean of the faculty of medicine of the University of London. Prof. Gask spoke on the decline of traditionalism. The address dealt in the main with the evolution of pharmaceutical education in Great Britain, indicating how in pharmacy as in other sciences there has been a progressive departure from old-established traditions, a process which has in recent years proceeded with increasing speed. It is the duty of the universities to encourage this. For hundreds of years the mind of man has been fettered by tradition. Advances were made in the nineteenth century, but they seem likely to be eclipsed by the achievements of this twentieth century, when the biochemist, the physicist, and the bacteriologist are daily contributing to the knowledge of the healing powers of Nature. Prof. Gask regards even these present advances as being transitional and as preceding even greater advances in the near future. The conditions of the present day do not favour a stereotyped, unprogressive civilisation, and to meet its requirements adjustment of thought and inventiveness are called for, and repeated criticisms of ourselves and our institutions.

AFTER Prof. Gask's address, a number of medals and prizes were presented by the president of the Society, Mr. A. R. Melhuish. The Hanbury Memorial Medal was presented to Prof. Hermann Thoms, of the University of Berlin. The medal, which is of gold, was instituted to commemorate Daniel Hanbury, whose name was well-known throughout Europe in the early half of last century for his accurate and painstaking investigations into the sources of vegetable drugs. The medal is awarded biennially by a Committee consisting of the presidents of the Pharmaceutical, Linnean, and Chemical Societies, the chairman of the British Pharmaceutical Conference, and one other member. The award is made " for high excellence in the prosecution or promotion of original research in the chemistry and natural history of drugs ". Prof. Thoms, who is the twenty-third recipient of the medal and the first German to receive it for twenty-six years, commenced his academic career with his appointment to the Pharmaceutical Department of the Friedrich Wilhelm University in Berlin in 1895. In 1900 he was entrusted by the Ministry of Education with the planning of the Pharmaceutical Institute of the University of Berlin, which was completed in 1902, and of which he was the director until 1927. Throughout his life Prof. Thoms has been an assiduous and prolific research worker, specialising in the chemistry of naturally occurring drugs. He was the founder of the Deutscher Apotheker Verein and for many years its president. The Pereira medal, which is regarded as the *cordon bleu* of pharmacy, was presented to Horace G. Rolfe. This medal is awarded annually by the Pharmaceutical Society as the result of a competition among recently qualified pharmaceutical chemists. It was founded to perpetuate the memory of Jonathan Pereira, at one time professor of materia medica to the Royal College of Physicians and also to the Pharmaceutical Society.

THE annual paper-reading conference of the Agricultural Meteorological Scheme organised by the Ministry of Agriculture and Fisheries was held at the Meteorological Office, Exhibition Road, South Kensington, on Oct. 8 and 9—Sir Napier Shaw being chairman, as in previous years. The meeting was well attended by research workers in various branches of agriculture. It is customary for a member of the staff of the Meteorological Office to read the opening paper. On this occasion Mr. E. G. Bilham, superintendent of the section of the Meteorological Office concerned with British climatology, opened with an account of various meteorological developments having importance for agricultural research, including an account of work that is being carried out with the view of obtaining a very much more complete representation of the distribution of monthly normal mean temperature over the British Isles than has been available hitherto. The underlying principle of this work is that a comparatively short period suffices to fix the differences between the normal mean temperatures of neighbouring places ; consequently, by comparing five-year means, of which a large number is available, using the indications furnished by a comparatively small number of places for which long-period normals are available as to the extent to which the monthly means for the five years in question were abnormal, a large number of comparable normals are obtained. As was pointed out, in estimating the effects of temperature on various agricultural phenomena by modern statistical methods, it is essential to be able to state the former variable as a departure from the normal.

THE nine papers that followed were contributed by agricultural research workers, and covered a large range of subjects, from the influence of climate on soil composition to the effects of light, moisture, and temperature on the growth of various pests and vegetable disease organisms as well as that of the crops on which these are parasitic. Among these may be mentioned a paper by Mr. L. Iorwerth Jones, in which the interesting experiment was described of interchanging samples of the soils at two different Welsh research stations of very different altitude in order to test the effect of mere climatic influences upon the growth of various grasses. The results suggested that comparatively slight changes of temperature and rainfall suffice in order to pass from conditions highly favourable to a particular grass to those so unfavourable that germination cannot even be achieved. These matters are obviously of the first importance in the choice of suitable grasses for laying down pasture, for which considerations of soil can clearly be given too much weight. The general tendency of the researches described in these meetings was to establish humidity as being one of the most vital meteorological factors in controlling plant growth as well as plant pests, but in one or two of the papers the light factor took the first place.

THE Report for 1930 of the Botanical Society and Exchange Club of the British Isles, by the secretary, Dr. G. C. Druce, gives an account of the activities of the Society during the year, including excursions to Galway, Co. Clare, and other places of special botanical interest. Sir Maurice Abbot-Anderson contributes an appreciation of the late Princess Royal, patroness of the Society; "she was a great lover of wild flowers and made many delightful paintings of them". Her place as patroness has been taken by H.R.H. Princess Mary, Countess of Harewood. "Plant Notes" for the year by the secretary and other members of the Society include reference to plants new to the British Isles, with critical notes, partly original and partly culled from other publications; and a list of new county and other records occupies fifty pages. A hundred pages are devoted to several original papers. These include a monographic revision of the larger British pondweeds, by Dr. W. H. Pearsall, which will be invaluable to students of this difficult genus; critical notes on brambles by William Watson; and some notes on British orchids by P. M. Hall. A supplement of special interest to British botanists is an account by H. A. Hyde of Samuel Brewer and a copy of his diary made during his botanical exploration in North Wales in 1727. This has been compiled from the transcript in the Banksian collections at the Natural History Museum, compared with one by Hugh Davies (1776) which has recently been acquired by the National Museum of Wales. The secretary also contributes a number of notes on new publications, and obituary notices of botanists, mainly British, who have died during the past year; there is also a full account of Dr. Druce's eightieth birthday celebrations.

THE Report is a remarkable tribute to the virility and inexhaustible energy of the octogenarian secretary. The Botanical Society was founded by Dr. Druce to extend and amplify the work of the old Botanical Exchange Club, and under his fostering care has developed to become a valuable helpmeet to British field botany and a record of results achieved. Anxiety as to what might happen when, in the course of Nature, the secretary lays down his work is, to some extent, allayed by an announcement in the Report. Dr. Druce states that he has left his "house, herbarium, library, paintings and furniture, with an endowment and a curator, as a Botanical Institute for the use of Botanists and a help to our own Society". An advisory committee which has been appointed contains the names of several well-known British botanists.

FIFTY years ago the Field Naturalists' Club of Victoria, Australia, was founded by a small body of enthusiasts, and at its jubilee celebrations in July it properly congratulated itself on the progress made during the years. The Club has kept in the forefront the ideals of the field naturalist, although it has had many members whose work lay along more specialised lines, such as Sir F. McCoy the palæontologist, Sir Baldwin Spencer, zoologist and ethnologist, and the members of the biological departments of the University of Melbourne. By popular evenings for talk and discussion, wild-flower and wild-nature shows, by championing the conservation of fauna and flora, its members have encouraged, with practical results, a love for Nature in the State. It has successfully advocated reservations as sanctuaries for fauna and flora, and owing to its suggestions and influence, in spite of indifference and opposition, Wilson's Promontory was set aside as a national park for the people. The record is a good one, and we share with the editor of the Club's magazine, the *Victoria Naturalist*, the wish that the centenary of the Club may be celebrated, not in a rented building, but in its own building, a hall of natural history on a central site in Melbourne.

THE sensational recovery of a homing pigeon, liberated in France in August, at Saigon on Sept. 9, has been attracting considerable attention in the press, and the episode is certainly a remarkable one, because the bird was a yearling on its first trial flight, and yearlings are not expected even to take part in any long-distance races, to say nothing of crossing a couple of continents. There is no doubt about the identity of the bird, the wing of which, says the Paris correspondent of the *Daily Mail* in the issue of Sept. 28, was stamped with the name and town of its owner, M. Louis Rasson, Dottignies. The bird must, of course, have gone hopelessly astray at the start, and may have got out to sea and been kept, or domiciled itself upon, an east-bound steamer; an Indian house-crow (*Corvus splendens*) has been known to board a homeward-bound steamer at Colombo, and remain with it until captured near Suez. But even if the passage were not assisted, the bird might work its way overland by consorting from time to time with other domestic pigeons and with the ancestral rock-doves, and thus learning how to find food and rest. In connexion with the long flights performed by these homing pigeons in races, it is a curious fact that the breed, which is, as opposed to the old black carunculated carrier, a composite one evolved in the last century, should show a decided tendency to have shorter wings than the sedentary dove-cot pigeon. The wood-pigeon, however, though largely migratory, has wings very much shorter than the rock-dove, a very sedentary bird.

SIZE fascinates, so we read with interest a new account of the habits of the largest of the 1800 known species of earthworms, *Megascolides australis*. We thought them to be rare, but Charles Barrett (*Australian Museum Mag.*, July 1931, p. 238) says that the rich dairy lands and potato fields of the lower Bass Valley are so thickly populated that thousands are turned up by the plough, and there the dark brown egg-capsules, buried from a few inches to several feet, are most easily found. It is not known in what form the soil swallowed by the worm is ejected, but the progress of the creature through its burrow is marked by gurgling and sucking sounds sufficient to startle the hearer. This is partly due to the lubrication of the tunnel walls by cœlomic fluid, ejaculated from dorsal pores, and this also appears in thin milky-coloured jets when the worm is irritated. Only one bird, the kookaburra, has been known to eat the giant worms, and even for it the meal is unusual. The worms may be three-quarters of an inch in diameter; the average length is a little more than four feet, but an hour's digging may produce several specimens six or seven feet long; and the largest actually measured was 11 ft. long. Several excellent photographs illustrate the size and habitat of the worm, which was filmed by the author.

A GOOD deal of misapprehension as to the commercial value of linking up large electric power stations so that they can mutually help one another still exists. This misunderstanding seems to be the basis of much criticism of the 'grid' in Great Britain. In the *Journal of the Franklin Institute* for August, N. E. Funk, the engineer of the Philadelphia Company, which is connected to two other huge companies by a 220-kilovolt link, gives a clear statement of the economic advantages of interconnexion. Five years ago, eleven companies extending from Chicago, Ill., to Boston, Mass., were interconnected. This led to many misconceptions in the press. For example, one paper said "1000-mile hook-up gives Boston light. Electric power interchange between New England city and Chicago; test is step in the development of single line from coast to coast!" It is pointed out that if power were transmitted from Chicago to Boston the cost of transmission would be about 5*d.* a unit, which is many times larger than the cost of generation in Boston. Interconnexion between power stations is desirable for several economic reasons. It increases the trustworthiness of the supply and decreases the number of dynamos that have to be held in reserve. As a rule also, the maximum demands of the various linked stations occur at different times, and this diminishes appreciably the amount of plant required. Mr. Funk proves that substantial savings can be effected by considering the case of his own company. The Pennsylvania Company with which it is linked supplies a mining, industrial, and farming section of the State. The Philadelphia Company and the Electric and Gas Company supply densely populated districts with very diversified demands. A chart is given showing the flow of current in a link with the power station during the course of a day.

MESSRS. Lanchester's Laboratories, Ltd., of Spring Road, Birmingham, have issued a pamphlet describing their loud speakers designed suitably for different purposes. In a picture theatre, for example, an instrument of great power is required. Its acoustical distribution also must be practically perfect and must have no directional bias. The firm make a large public address outfit which will broadcast speech over a radius of a hundred yards in the open, every syllable being distinctly heard and the identity of the speaker being recognised. They also make a smaller model suitable for a small receiving set or a radio-gramophone in the home. When compared with the loud speakers on the market a few years ago, they show great improvements and a very considerable reduction in price. A helpful attempt is made to explain exactly what is meant by a 'decibel'. It is pointed out that this is the logarithm of a ratio and so is incorrectly described as a unit. In the appreciation of sound it takes a drop of twenty per cent in the intensity as received by the ear before it is noted that there is a drop of volume. Plus or minus one decibel is the least change of intensity that the ear will notice under the most favourable conditions. Without special attention, plus or minus three decibels is about the smallest difference that is noticeable. This corresponds to the wide difference of two-to-one in the energy received. It is fortunate that this is so, for when listening to an orchestra some of the audience owing to their positions hear the various instruments in widely different proportions. If it were not for the adaptability of the ear, the music would sound very differently in various positions. Very simple home tests are given for testing a loud speaker.

IN response to many urgent appeals from those interested in archæology and anthropology, the exhibitions arranged in connexion with the centenary meeting of the British Association, at the Wellcome Historical Medical Museum, 54 Wigmore Street, London, W.1, will remain open until Oct. 31. The Museum will be open each day, excluding Sundays, from 10.30 A.M. until 5.30 P.M., admission free. The Egyptian Exhibition includes the results of past seasons' excavations carried out by the Egypt Exploration Society at Tell el Amarna and Armant, under the leadership of Mr. J. D. S. Pendlebury and Mr. O. H. Myers. A remarkable collection of ancient, rare, and precious jewels and ornaments from Egypt has been lent by foreign and British museums, as well as numerous collectors at home and abroad, in response to requests made by Dr. Robert Mond. Realistic models are extensively employed for the first time to illustrate the structure and character of ancient Egyptian palaces, tombs, and methods of excavation. In the Amarna Section, the head of a princess is a distinct acquisition to the art of the period; while the model of a nobleman's palace, like the reconstruction of a sacred bull burial from Armant, tells at a glance what hours of reading and study would not make clear. Associated with the Egyptian Exhibition is a noteworthy collection of photographic studies of various phases of South African life by Mr. Duggan-Cronin and Dr. L. Cipriani, of Italy. There is also the interesting exhibit from the English Folk Dance Society, illustrating customs of past centuries in England.

A number of very successful transmissions by television were recently carried out from a portable transmitter installed in a studio of the British Broadcasting Company. Arrangements have been made by the B.B.C. and the Baird Company to investigate whether a wire link can be used to carry the television signals in sufficient strength and purity to enable the North Regional Station at Slaithwaite to repeat the transmissions. Should these experiments be satisfactory, then it will be possible for owners of 'televisors' in the north to obtain very much better reception of television broadcasts than they have had up to the present. We learn from the October number of *Television* that the B.B.C. has agreed to admit television within the recognised programme hours. The transmission is being broadcast from a B.B.C. studio on one evening every week. Some of the radio artistes at the B.B.C. form the studio 'subjects', so that the owners of televisors are able to see them on the screen.

Negretti and Zambra's new catalogue of meteorological instruments (List M.2) is a worthy successor to the firm's monumental catalogue of engineering and industrial instruments (List E.5) published about two years ago. It contains much useful information in regard to points of practical importance in the design and use of instruments and a number of references to published work. In the foreword it is made clear that very harmonious relationships exist between our biggest firm of meteorological instrument makers and the Meteorological Office. Without close and sympathetic co-operation between the official meteorological service and the instrument makers little could be achieved, and it is all to the good that there should be a free interchange of ideas. The result is that the ordinary purchaser can obtain from the maker instruments similar in every respect to those supplied for use at official stations, and can feel assured that they represent the result of years of endeavour to produce the most suitable type of instrument for the purpose it is to serve. Besides an ample choice of the usual instruments for meteorology, particulars will be found of aircraft and upper air instruments and also of test apparatus—a particularly useful section. In connexion with tube anemographs (pp. 16-17) mention should be made of the fact that a Meteorological Office certificate in respect to the recording unit can be supplied at a small extra cost. In the thermometer section the 'sheathed' pattern instruments M.2135, M.2136, and M.2176 are of special interest. The numerous advantages conferred by this type of construction have recently been recognised by the Meteorological Office and it has been adopted as the official pattern for use on land. It is due to Messrs. Negretti and Zambra to point out that they have listed similar instruments for many years. Prospective purchasers should note, however, that the Stevenson screen requires special fittings to support them.

The Annual Congress of Radiology and Radiological Exhibition will be held at the Central Hall, Westminster, on Dec. 2-4.

The following appointments have recently been made by the Secretary of State for the Colonies: Mr. J. A. Baker, to be agricultural field officer, Malaya; Mr. J. N. Clothier, to be agricultural officer, Northern Rhodesia; Mr. H. M. Stent, to be assistant agricultural research officer, Northern Rhodesia; Mr. L. E. W. Codd, to be plant breeder, British Guiana; Mr. W. J. M. Irving, to be agricultural officer, Uganda; Mr. L. N. H. Larter, to be geneticist, Agricultural Department, Jamaica; Mr. P. Morrison, to be manager of the Government Fruit and Vegetable Bureau and supervisor of Agricultural Credit Societies, St. Vincent.

The memory of the late Mr. Andrew Laing as one of the great engineers of this century, and of his activities in the cause of the advancement of the sciences of engineering and shipbuilding, are to be perpetuated by an annual memorial lecture to be given under the auspices of the North-East Coast Institution of Engineers and Shipbuilders. Mr. Laing, who died on Jan. 24, 1931, was the general manager and a director of the Wallsend Slipway and Engineering Co., Ltd. The memorial lecture is made possible through the munificence of the Misses Jeannie and Catherine Laing, who, being desirous that a special fund should be founded to perpetuate the memory of their brother, have transferred into the name of the Institution the sum of £2000 for the purposes of the lecture.

In recognition of his outstanding work in the science of ornithology, particularly as applied to bird migration, Dr. Witmer Stone, vice-president of the Academy of Natural Sciences of Philadelphia, and curator of its department of vertebrate zoology, has been awarded the Otto Hermann medal of the Hungarian Ornithological Society, the highest honour conferred by that organisation, and one of the most significant of its kind. This medal commemorates the distinguished achievements of Dr. Otto Hermann, whose research in bird migration gave him high rank among ornithologists, and whose death in 1914 was a world loss to this science. For many years he had devoted his entire time to an intensive study of zoology, especially bird life and habits, and it was largely through his efforts that the Museum in Budapest was developed to its present excellence.

THE ninth International Congress of the History of Medicine will be held at Bucharest, under the presidency of Dr. V. Gomoiu, next September, when the principal subjects for discussion will be (1) the evolution of medicine in the Balkan States and (2) the protection of Europe against bubonic plague. Those wishing to contribute papers on these or other subjects are requested to forward the title and a typed copy of a summary of their paper to the office of the Congress, Str. Stirbey Voda 86, Bucharest II, without delay. The official languages will be English, French, German, Italian, and Spanish. Members of the Congress can take the direct route to Bucharest or meet at Trieste, whence visits will be paid to Athens, Constantinople, and Constantza, where local committees will be arranged for their reception. The meetings of the Congress will occupy four days, and the following three days will be devoted to a tour of Bucharest and excursions in the neighbourhood. A programme will be issued later giving the exact date of the Congress and the amount of the subscriptions.

THE journal entitled *La Géographie*, published by the Société de Géographie of Paris, has had a career of more than a century in one form or another. It has now undergone another change, and with the September issue appears with the title of *Terre Air Mer*. In its new form it is to treat more of descriptive and economic geography; and to adopt a more popular outlook than of old. The illustrations are increased in number, and the detailed bibliographies seem to have been given up. An article on the influence of Pierre d'Ailly on Columbus is of interest.

ANOTHER series of the excellent post-cards illustrating British trees has been issued by the British Museum (Natural History), S.W.7, each set containing photographs showing the habits of the tree in summer and winter and coloured illustrations of the flower and fruit. With each set there is a description of the tree and of characteristics that have given its timber or other products a practical interest. These sets of four cards in a neat envelope at sixpence should find wide use in schools, and are well worth purchase by those interested in the common trees of the countryside. The term 'British' is employed to include various well-known and common trees which are, strictly speaking, not native; thus, the larch is included in these new issues. Now the number issued is becoming so extensive, it would be a desirable innovation if, with each set of four, a list of the trees available in the series were included.

UNDER the title of "Orthoptera Celebica Sarasiniana I." the supplement to Vol. 12 of *Treubia* (May 1931) contains a series of papers on the saltatorial Orthoptera of the Celebes. It deals with material obtained by the Sarasins a number of years ago, besides later discoveries made by others. The most extensive contribution is by Mr. H. H. Karny on the grasshoppers of the family Tettigoniidæ and their geographical distribution. This same authority also deals with the family Gryllacridæ, while Mr. L. Chopard writes on the Achetidæ and Gryllotalpidæ, and Mr. C. Willemse discusses the Acrididæ. While a number of new species are described, those already known and their respective genera are diagnosed in detail, and the descriptions are accompanied by numerous text figures illustrating various morphological features. The whole work, when completed, will form a comprehensive monograph of the Orthoptera of the Celebes, and will prove valuable both to students of the order and to entomologists interested in problems of geographical distribution.

THE Medical Research Council has issued a third edition of the "Catalogue of the National Collection of Type Cultures" (Special Rep. Series, No. 64. H.M. Stationery Office; 2*s*. net). The collection is maintained by the Council at the Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W., Dr. St. John-Brooks and Miss Rhodes being the curator and assistant curator respectively. The collection now exceeds 3000 different strains of micro-organisms, and cultures will be supplied so far as possible on application to the curator, a small charge being made to defray costs. The co-operation of microbiologists is invited, and they are asked to deposit in the collection not only new species or important strains of organisms but also strains of recent origin of the commonest types. Some particulars are given in the preface on the present position of bacterial classification and nomenclature and of the Nomenclature Committee of the International Society for Microbiology.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in mathematics at the Training College for Teachers, University of Rangoon—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (Oct. 22). A headmaster of the Euclid Street, Swindon, Secondary Co-Educational School—The Secretary to the Swindon Education Committee, Clarence House, Clarence Street, Swindon (Oct. 31). A professor of zoology in the University of Sheffield —The Registrar, University, Sheffield (Nov. 4). A Geoffrey Duveen travelling student in oto-rhino-laryngology at the University of London — The Academic Registrar, University of London, South Kensington, S.W.7 (Dec. 31). A chief lecturer in chemistry at the Woolwich Polytechnic—The Principal, Woolwich Polytechnic, S.E.18. A teacher in charge of the chemical department of the Barnsley Mining and Technical College—The Principal, Mining and Technical College, Barnsley. A head of the department of civil and mechanical engineering of the Huddersfield Technical College—The Director of Education, Education Offices, Peel Street, Huddersfield.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The 'Lapides palmati' mentioned in the "Historia Naturalis" of the Elder Pliny.

Pliny, in Book 36, par. 134, in the course of a description of various minerals, says, "Palmati (sc. lapides) circa Mundam in Hispania, ubi Caesar dictator Pompeium vicit, reperiuntur, idque quotiens fregeris". (Stones marked with the pattern of a palm, which appears however often you break the stone, are discovered near Munda in Spain, where Cæsar, during his dictatorship, defeated Pompey.)

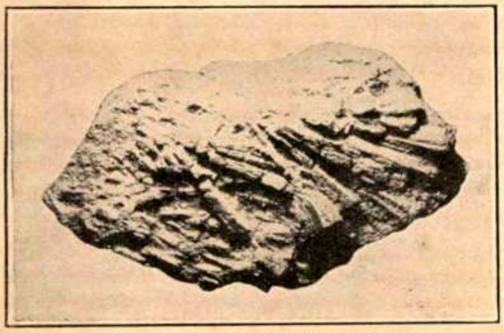

Fig. 1.—Andalusite in mica schist.

So far as I am aware, no attempt has been made to identify these stones, beyond the almost certainly incorrect suggestion that they were fossils of palm leaves. Munda, near which Cæsar defeated Labienus and Cneius Pompeius in 45 B.C., was situated in the province of Spain called Andalusia, and the aluminium silicate, andalusite, which derives its name from that locality, answers Pliny's description well and in two different ways.

In the first place, occurring in argillaceous schist, mica schist, and other rocks, it often forms radiating groups of prisms which bear a remarkable resemblance to branches with thin spiky leaves. Fig. 1 shows a specimen in mica schist from the Geological Museum of Trinity College, Dublin. Although, however, the words "idque quotiens fregeris" might describe the finding of a palm-like pattern of crystals when the parent rock is broken, it seems more probable that they refer to a still stranger property of the mineral. A variety of andalusite known as chiastolite (χιαστός, arranged diagonally) or macle (*macula*, a spot) consists of "stout crystals having the axis and angles of a different colour from the rest, owing to a regular arrangement of carbonaceous impurities through the interior, and hence exhibiting a coloured cross, or a tesselated appearance in a transverse section". The pattern is discovered wherever the crystal is split ("quotiens fregeris"), and Fig. 2, taken from Miers' "Mineralogy", p. 50 (second ed.), shows that the pattern may sometimes bear a great resemblance to palm branches. The chiastolite variety occurs, among other places, at Morbihan in Brittany, and Andalusian specimens, found in Pliny's day, may well have shown the phenomenon. Dana ("System Min.", 1904, p. 497), from whom the words in quotation marks are taken, reproduces pictures of other chiastolite patterns.

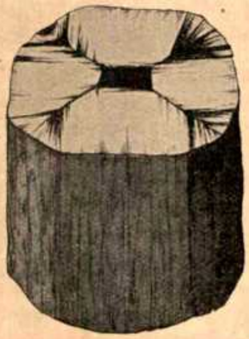

Fig. 2.—Chiastolite pattern. From Miers' "Mineralogy" (by kind permission of Macmillan and Co.).

My thanks are due to Dr. Louis B. Smyth, and to my wife, for suggestions and assistance in arriving at this identification.

Eclipse Plumage in the Mallard.

The reasons for the changes of pattern, colour, and type in the plumage of fowls have been the subject of investigation by many workers and the parts played by testis, ovary, and thyroid shown. Work has also been carried out on ducks, the reactions of testis and ovary receiving most attention. Goodale,[1] Seligmann and Shattock,[2] Kuhn,[3] and others found little correlation between the eclipse plumage of the mallard and testis size and function or ovarian influence.

The experiments on ducks which I describe briefly below were undertaken because it was thought that a wider study of the relation between the endocrines and plumage modification would be profitable.

The mallard (*Anas boscas*) was chosen as being the most responsive material, the drake having two regular changes of plumage type during the year—eclipse plumage from May to September and mating or normal plumage from October to April.

The aim of these experiments was to produce the eclipse plumage in these drakes during their mating plumage season, October to April. Before each experiment, areas of feathers were plucked on breast and belly, and, in the pituitary work, on the flanks.

A start was made with thyroid, on the lines of the experiments of Greenwood and Blyth,[4] and others in which the colour of the neck hackles of the Brown Leghorn cock was changed from gold to black by the feeding of thyroid. No parallel change occurred in the mallards though a similar preparation was used and the amounts fed approximated to the higher dosages given to the fowl. The thyroid feeding appeared to cause only an alteration in the pattern rhythm of the growing belly feathers—their colour was unaltered and the breast feathers showed no change. It was noticed also that large single doses of thyroid that caused precipitate moulting in cocks had no similar effect on the drakes.

Pituitary was next tried. Desiccated anterior lobe suspended in saline was injected subcutaneously into drakes, with the result that the growing feathers in all plucked areas showed modifications in pattern and colour. Except in the breast feathers of two drakes, these modifications approximated to the normal eclipse plumage exhibited later by each drake.

At the same time other drakes were given subcutaneous injections of dried posterior lobe suspended in saline. Here, though there was modification in pattern and colour, the modified pattern and colour differed from the normal eclipse feathers shown later by each drake, from those produced by the anterior lobe injections, and from the modified pattern of the belly feathers produced by the thyroid feeding referred to above. There appeared to be a change of the pattern rhythm and intensity of pigment deposition.

Injections of whole pituitary gave varied results, and further work on this is being done.

These isolated results can contribute nothing conclusive to our knowledge as to the cause of eclipse plumage. Further experiments are in progress on the relation of the other endocrines to eclipse, mating, and female plumage. When these further experiments have been carried out and the full analysis is completed, it is hoped that interesting results on the subject of the endocrine modifications of plumage expression within the range of gênetic determination will be obtained. Change of Density of Carbon Disulphide with Temperature.

THE investigations of Isnardi[1] have shown that the value of the dielectric constant of carbon disulphide falls suddenly at −90°. This drop appears at a considerable distance from the freezing point (−112°), so the phenomenon shows an analogy to the change of the dielectric constant of ethyl ether with temperature. On the basis of this analogy, it might be reasonably supposed that the values of other physical properties of carbon disulphide would show similar abrupt if less marked changes at −90°.

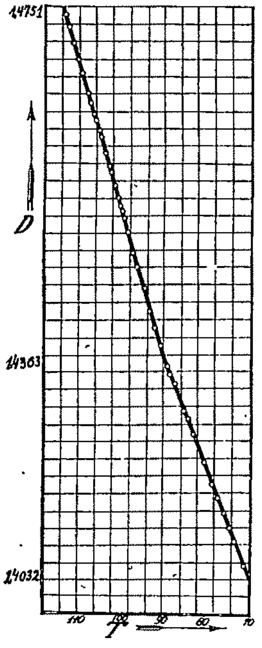

FIG. 1.

Experimental investigation has shown that on the heating curve of carbon disulphide there appears at −90° a distinct slowing down of rate of change of temperature. This suggests a change of the substance at this point from one liquid modification into another liquid modification. The analysis of the heating curve has enabled us to evaluate the latent heat for this change.[2]

The next step consisted in a study of the changes of density of carbon disulphide with temperature, with special attention to the neighbourhood of −90°. I have therefore measured the density of carbon disulphide, using the method described by Kamerlingh Onnes and I. D. Boks. The details of the experiment have been described by me in the communications concerning the densities of ethyl ether and nitrobenzene.[3]

The temperatures were determined with an error not greater than 0·003°. The position of the meniscus of liquid could be read with an error of about 0·2 mm.; this corresponds to an uncertainty of 1·5 mm.^{3} in the value of volume of the liquid, so that, taking into account the volume of the dilatometer bulb, the relative error in the value of volume was about 0·1° per cent. The mass of the substance was determined with an error of about 0·0001 gm.; it follows that the values of the density were certain up to the fourth or even fifth figure.

As a freezing liquid I have used a mixture of ethyl ether and ethyl alcohol, mixed in a certain proportion. This mixture remains clear with the lowering of temperature, and it does not impede the motion of the stirrer even at −120°.

I may mention that the values of temperature were determined by means of the platinum resistance thermometers placed in the Dewar vessel at different depths. The determinations of temperature were made only after it was certain that the temperature was stationary throughout the volume of the freezing liquid. When the temperature of the freezing liquid was lowered down to −120° C., further cooling was stopped, whereas the stirrer remained in motion. Under the influence of the heat of the surroundings, the temperature of the carbon disulphide in the Dewar vessel increased slowly at the rate of about 1° per hour.

The carbon disulphide used in this investigation was very carefully purified, starting from the pure Cl_2 " pro analysi " delivered by Schering-Kahlbaum. The accompanying curve (Fig. 1) shows the change of density of carbon disulphide in the interval of temperatures between 112° C. and 70° C. It appears that with the lowering of temperature the density of carbon disulphide increases from the value 1·2628 at 20° up to 1·4363 at 90°. At this temperature there begins a more rapid increase of density with lowering of temperature. In the neighbourhood of the freezing point the density has the value 1·4751.

It appears, therefore, that at the point of change from one to the other liquid modification of carbon disulphide the density curve shows a distinct change of slope. J. MAZUR.

Deep-Focus Earthquakes.

MR. F. J. SCRASE[1] has recently found confirmation of the great depth assigned to certain earthquakes by the late Prof. H. H. Turner by recognising, in the data of the International Seismological Summary, the two separate branches of PR_1 and SR_1 that are to be expected if the focus be deep, and by observing the substantial agreement of their travel-times with the expected times calculated on the basis of the Zoeppritz-Turner tables. It may be of value to note in this connexion that we may, by the use of these reflected pulses, arrive at what is certainly a minimum value of the depth of focus, and this independently of any previous travel-time tables and even of any error in the assumed time of origin. This would eliminate any objection that might possibly be made to the use of the Zoeppritz-Turner tables.

All that is needed is good curves, derived from the data of the earthquake being investigated, showing the arrival times for P and for pP (this latter being the notation suggested by Scrase for a P wave reflected close to the epicentre). It will be seen from such curves that the interval $pP-P$ gradually increases with increasing epicentral distance, though the two curves soon become nearly parallel. At a distance of 180°, where the slope of the two curves becomes equal to zero, the interval would represent exactly twice the time required for a wave to travel from focus to epicentre. Curves extending to that distance are not generally obtainable. However, we may choose a point where the two curves are almost parallel, say at 90°, and the perpendicular distance from a point on the P curve to the pP curve will approximate to the distance between the curves at 180°. By a suitable correction this approximation can be made still more exact. Hence, if this given distance corresponds to a time interval of 100 sec., we know that the focus is at least at such a depth that a P wave requires 50 sec. to travel to the epicentre. Multiplying this time by an average value of the velocity at moderate depths, we arrive at a value for the depth of focus. The above-mentioned interval of 100 sec. would thus indicate a focal depth of approximately 400 km.

Records from observatories throughout the world for an earthquake of March 29, 1928, have yielded very satisfactory curves for P and pP, for S and sS, as also for other pulses. The uncorrected distance between the P and pP curves corresponds to an interval of 92 sec., so that great depth of focus seems well established. Several other features of the records point in the same direction. This conclusion is further confirmed by Wadati's assignment,[2] on the basis of the records from the nearby Japanese stations, of extraordinary depth to this shock.

It is felt that the admission of the occurrence of earthquakes at depths of the order indicated must entail interesting consequences for speculations in regard to the earth's structure and constitution.

A Counting Device for Use with the Geiger Counter.

THE most trustworthy instrument for recording the impulses delivered by a Geiger counter is no doubt a string electrometer. Since, however, the counting of the deflections on a photographic record requires a good deal of time, a mechanical summation will in general be preferred. The arrangement to be described here has the advantage of being so simple that it does not require any watching, even throughout long series of observation.

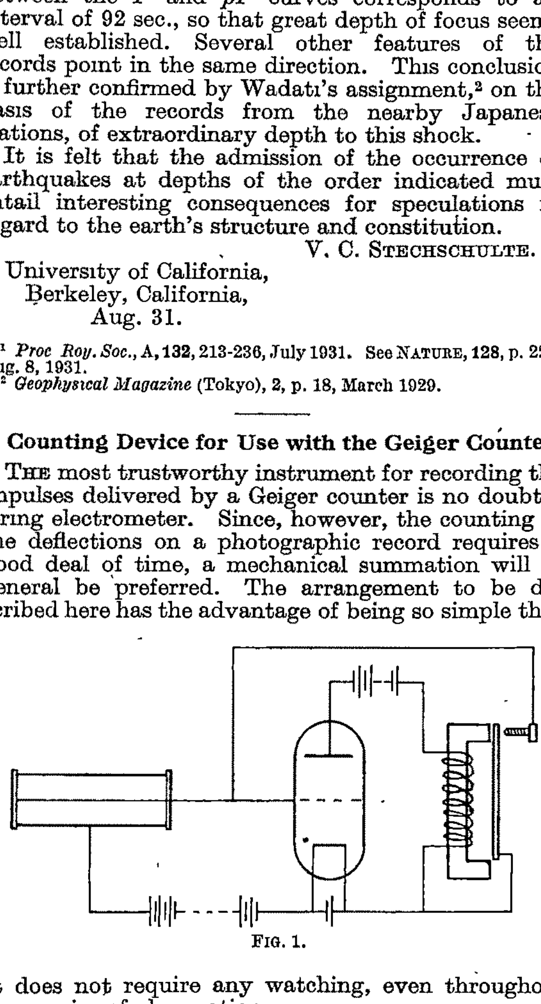

FIG. 1.

The positive (central) electrode of the counter is connected to the grid of an ordinary 3-electrode valve giving an anode current of 20-30 ma. when the grid is free (Fig. 1). To improve the insulation of the grid, the lead-in wire is pulled out through a hole drilled in the side of the bakelite socket and fixed in a plug of ebonite or amber. The anode current of the valve is sent through the coil of an ordinary telephone call meter; the screw which determines the movement of the yoke is insulated and connected to the grid. The yoke is connected to the negative end of the filament. The voltage swing applied to the grid by an impulse from the counter may easily attain a value of 50 volts and under ordinary working conditions is 20-30 volts, which is sufficient to break the anode current of the valve.

When the whole is at rest, the potential of the grid is nearly the same as the negative end of the filament; the anode current has the corresponding value, and the yoke of the counting machine is attracted by the magnet. Upon the arrival of an impulse from the counter, the anode current is broken, and the yoke is released; as soon as the yoke touches the screw, the anode current is raised again to its normal value.

The connexion of the grid to the insulated screw is necessary; when the grid is brought to a negative potential of 20-30 volts and left to itself, it would remain at this potential for a considerable time, since no grid leak is used.

The number of impulses should generally not exceed 200 per minute; when the number is higher, a considerable number of impulses may be lost. This seems for the main part to arise from the counter itself, a certain restoring time being necessary after each impulse.

Effect of Light on the Surface Tension of Boys's Soap Solution.

THE letter of Prof. L. D. Mahajan in NATURE of Sept. 19, p. 496, which brings forth an interesting point, may be slightly misleading, inasmuch as it tends to indicate that time, or rather adsorption as a function of time, is only a negligible factor in the decrease of the surface tension of colloidal solutions, which I pointed out in 1924.

Even before Dr. Mahajan's memoirs are published, I feel that I must remind the reader who is interested in these questions that the conditions of Dr. Mahajan's experiments are quite different from those on which I based my interpretation of the experimental facts, and that consequently it is premature to issue a general statement.

I have shown, indeed, that the 'time-drop' was small for high concentrations, such as 1 per cent, and that it increased as the dilution increased. For example, one sample would give a drop of 2 dynes at 1 per cent and 20 dynes at 1 per hundred thousand, or 10^{-5}. I explained the difference, and studied thereafter only high dilutions up to 10^{-7}, under subdued artificial light.

Now Dr. Mahajan states—without specifically limiting his statement to sodium oleate solutions—that "the decrease in surface tension is a function of the time for which the solution is exposed to light and not a mere function of the time". As the concentration of the *soap solution + glycerin* which he uses is not stated, but may be as high as 2·5 per cent—which should give a very small drop—it is indeed quite possible that illumination plays a part in this case. But this does not substantiate the general statement that even in the case of high dilutions, where the drop is considerable, "a possible reason for this is a chemical action, not adsorption in the surface layers alone".

I shall look forward with much interest to Dr. Mahajan's papers, but as some readers may not see them, I think it advisable to direct their attention to the fact that the experiments reported in his letter cannot suffice to weaken my former interpretation.

Fine Structure in the Arc Spectra of Indium and Thallium.

Indium.—The hyperfine structures of a few indium arc lines have been reported by Jackson[1] and McLennan.[2] Jackson observed that each of the lines $1\,{}^2S_{\frac{1}{2}} - 2\,{}^2P_{\frac{1}{2}}$ and $1\,{}^2S_{\frac{1}{2}} - 2\,{}^2P_{\frac{3}{2}}$ is a quartet; while McLennan observed only three components. McLennan deduced a value $i = \frac{1}{2}$ for the nuclear moment, while Jackson, from intensity considerations and the structures of the lines, inferred $\frac{7}{2}$ as the more probable value of the nuclear spin.

The fine structure patterns are not generally completely resolved, owing to the lack of resolving power in the interferometer and owing to the effect of electric fields and pressures in broadening the spectral lines. The fine structure measurements of the lines 4511, 4101, 3259, and 3256 A. have recently been made by me, using a specially constructed vacuum arc of 2 per cent amalgam of mercury and indium with cathode and anode cooled. Owing to the extremely low partial pressure of indium vapour, the lines were found to be extremely sharp and without self-reversal in this source. The fine structure was examined by a quartz Lummer plate (200 × 30 × 8 mm.) and quartz and glass plate etalons. The photographs clearly show the complex structure found by Jackson. A careful examination of the fine structure and the intensity value of the components indicate that the most probable value of the nuclear movement is $\frac{5}{2}$ or $\frac{7}{2}$.

Thallium.—Fine structure measurements of arc and spark lines have been recently reported by Schuler[3] and McLennan.[4] The fine structure of the arc lines 5350, 3776, 3529, 3819, and 2768 A. has been examined by me by employing experimental arrangements similar to those for indium: 3776, 3524, and 3519 were observed in detail. The structure of 3776 was observed under different conditions of excitation, and it is found to have five components.

3776 and 2768 show more hyperfine structure components than required by theory for $i = \frac{1}{2}$, and there is evidence of a weak isotope with the same nuclear moment. The observations confirm the value $i = \frac{1}{2}$ for the nuclear moment suggested by Schuler and McLennan.

Full details of these fine structure measurements will appear shortly in this Observatory's bulletin.

The Magneto-Electric Saturation Effect.

As is well known, all previous investigations performed in order to find a magneto-electric saturation effect have led to a negative result. This is of importance for the classical theory of Langevin as well as for the wave theory. It would therefore seem to be of importance to try to find this effect by the help of new methods. In this note we propose to give an outline of the main feature of our method and the results obtained. The theory and the observations will be published later.

According to the new theory of strong electrolytes given by Debye, we know that the electric field of the ions has a great influence, for example, on osmotic phenomena and electric conductivity. At a distance of the same order as the diameter of an ion a field of force is produced of the magnitude 10^6 volts/cm. Let us consider a solution of a strong electrolyte, for example, potassium chloride in water. This electrolyte is separated in K^+ and Cl^+ ions. Add to this solution neutral molecules which are carriers of electric dipole moments. Due to the field they will, for example, in the proximity of a K^+ ion, orient themselves in the direction of this ion; naturally in equilibrium with their thermal motions. Assume that these neutral molecules that have electric dipole moments also possess magnetic moments fixed to the molecules.

The conditions now being clearly stated, the following experiment will be understood. The apparent magnetic moment of molecules which possess fixed magnetic as well as electric moments must be decreased by adding to the solution a strong electrolyte. We have calculated the magnitude of this effect on the basis of the classical magnetic theory. Measurements of the magnetic susceptibility have been performed by aid of Quincke's method improved by Piccard.

The observations have been performed on a solution of $(Cr(NH_3)_3(CNS)_3)$ in acetone by adding KCNS as a strong electrolyte. The results are decidedly negative. The experiments therefore are in favour of the new wave theory of paramagnetism.

Electric Circuit Breaker Research.

During the continuation in February, March, and August 1928 of tests commenced in 1926 by the Circuit Breaker Research Section of the British Electrical and Allied Industries Research Association, highly inductive power circuits of 6600 volts carrying more than 1000 amperes were successfully broken in oil, at gaps of from one-fifth to one-eighth of an inch, in an experimental circuit breaker of novel design. It was not found practicable to use smaller gaps, owing to the possibility of beads of copper forming, reducing the arc gap; thus it was not possible with the maximum voltage of 6600 volts then available to determine accurately the true dielectric strength per cm. at arc break.

Recently, through the courtesy of Dr. S. L. Pearce, of the London Power Co., Ltd., we have been able to carry our investigations up to 22 kv.

In these tests, which were carried out from Sept. 8 to Sept. 17, 1931, an arc current of 500 R.M.S. amperes was extinguished in an oil-immersed electrode gap, before the electrodes had separted half an inch (in a highly inductive circuit using power transformer stepping up from 6600 volts to 22,000 volts and giving a recovery voltage of 21,000 R.M.S. volts across the single arc gap in use). Seven repeat tests were made under the same conditions; the arc was in several cases extinguished before the separating electrodes had reached a gap of one-fifth inch, corresponding to a dielectric strength of over 100,000 volts per inch, gained within a few micro-seconds from the time when the arc current had reached a zero in its alternation.

As an indication of the advance made, it may be mentioned that an average figure for the dielectric strength at arc extinction in plain break oil circuit breakers is of the order of 2500 volts per inch at similar currents.

Research Items.

An Alleged Moose-Wapiti Hybrid in Montana.—*California Fish and Game* (vol. 17, p. 198; 1931) contains a reference to what is said to be the first known specimen of a 'moose-elk', or in our nomenclature a 'moose-wapiti', hybrid. Known to the United States forest rangers as "the elk with the funny horns", this curious cross was recently killed in the Deerlodge National Forest, Montana. The rangers had for the past five years known of the animal, which associated and grazed with the wapiti, but the horns and the body of which were half moose and half wapiti. When first seen in 1925 he appeared to be about a three-year-old, and his weight when slain was 1100 pounds. Our impression is that so rare and odd a hybrid deserved a much more detailed obituary notice, since experience shows that there is often the possibility of an abnormal member of one species being regarded as a cross with another.

Bird Migration in Switzerland.—An important contribution to the migratory movements of birds in Switzerland, founded upon field-observation and ringing, and summarising in all 16,500 data for the spring movements and 5600 for the autumn, is made by Dr. Konrad Bretscher (*Mém. Soc. Helvét. Sc. Nat.*, vol. 66, mem. 2, 1931). The data cover long periods and refer to sixty-eight species in spring and forty-nine in autumn. There is general agreement between the information gained from the two methods of observation, and the results indicate that the main migratory route lies through the Great Valley between the Alps and the Jura mountains. In spring the journeys run from south-west to north-east, and in autumn take the reverse direction. A second important route lies over the northern Jura, in spring in an eastern, in autumn in a western direction. The northern Alpine valleys are peopled by side movements from the Great Valley, whereas the southern valleys receive their birds from the south, so that both sides of the mountain chain contribute to a cross-migration, in which it is impossible to separate the elements. Further researches, especially by the ringing method, must be made before an understanding can be reached of the movements in the Alps, particularly in the Wallis and Engadine districts.

Weevils of Samoa.—Part 4, Coleoptera, Fascicle 5, of "Insects of Samoa" in course of publication by the British Museum (Natural History), is concerned with the Curculionidæ or weevils of those Islands. Sir Guy Marshall, who is the author of the present contribution, remarks that ten years ago only 22 species of these insects, comprised in 15 genera, were recorded. He is able now, as the result of his studies, to raise these numbers to 86 species belonging to 55 genera, of which 54 species and 15 genera are described for the first time. Only eight of these species are known to occur outside the Pacific islands, and of the remaining 78 species, no less than 80 per cent must, at present, be regarded as being peculiar to Samoa. A study of the different genera of these insects appears to suggest that the Samoan fauna has been derived from the Malay Archipelago by way of New Guinea and not from the south. Since too little is known of the insects of Tonga and Tahiti, it cannot be determined how far they are related to those of Samoa. All that can be said is that the insects of the last-mentioned islands show, on present indications, most affinities with those of Fiji. Sir Guy Marshall's memoir, it may be added, is a noteworthy contribution to a knowledge of the family Curculionidæ, and is admirably illustrated by figures drawn by Mr. A. J. Engel Terzi.

Industrial Shells of the Philippines.—F. Talavera and L. A. Faustino (*Philippine Jour. Sci.*, vol. 45, No. 3; 1931) report on the shells gathered on a commercial scale in the Philippines. The gold-lip pearl shell (*Pinctada maxima*) is utilised primarily in the manufacture of buttons, but other objects, such as knife handles, are made from this shell. Preliminary experiments on culture pearls in 1929 were encouraging; shell-beads 5 mm. in diameter introduced into two-year old 'oysters' had increased at the end of thirteen months to 7 mm. The black-lip pearl shell (*P. margaritifera*) is more widely distributed. The shell, which reaches a diameter of 9 cm., is used for the making of buttons, of inlaid work, cameos, etc. The majority of the *Trochus* shells collected are of *T. niloticus*, and are found chiefly on the islands near the outer edge of the coral reefs. Closely associated with the last species is the green turban shell (*Turbo marmoratus*). Both are used in making buttons and other objects. The window shell (*Placuna placenta*) supports an industry of considerable importance. Although usually found in the littoral zone this species is known to live in water 40 metres deep; it flourishes in mud or sand-mud bottoms in shallow bays and in estuaries. Fishermen in certain regions transplant undersized examples to better grounds. The shell, which reaches a diameter of 55-77 mm. at the end of the first year of growth and about 133 mm. at the end of the second year, is used instead of glass for window panes, shades, etc. The pearly nautilus (*N. pompilius*) is taken in deep sea bamboo traps set to capture bottom fish, and its shell is being used in the manufacture of lamp-shades, spoons, etc.

Life-Cycle of *Moniezia expansa*.—D. F. Sinitsin (*Jour. Parasit.*, 17, June 1931) records observations on the egg of the cestode *Moniezia expansa*. The adult tapeworm lives in the small intestine of sheep, and ripe segments containing the eggs are passed with the excrement. The author describes the three envelopes of the egg, which contains a capsule composed of a spherical body and two tapering horns. In the body of the capsule is the six-hooked embryo and an apparatus for feeding the horns. Experiments extending over forty-five days, during which the eggs were repeatedly dried, showed that the shell provides very efficient protection against desiccation, and the author concludes that under normal conditions in Nature the egg does not reach its prospective host at once, but is destined to be at large rather a long time. In the later period of the experiment the egg shell became very fragile; the slightest touch broke it and freed the capsule with its horns, one of which is twisted round the other at this time. If the horns come in contact with a moist surface they untwist and form a boring apparatus. The mucus of the trachea brings about this boring action, and causes the solution of the capsule in less than thirty minutes. The author concludes that an intermediate host is lacking in the life cycle of *Moniezia expansa*. "The embryo, after a period of about two months' development in moist materials, returns again to the sheep by the air. Perhaps it enters the capillaries of the windpipe or alveoli, and, by the aid of the circulatory system, eventually reaches the intestine."

Mutable Genes in Delphinium.—Two mutable genes in *Delphinium* are the subject of a paper by Demerec (*Jour. of Genetics*, vol. 24, No. 2). The rose-alpha gene is unstable, reverting to the wild purple type of cell both in the sepals and petals (causing purple spots) and in the germ cells. By measuring the sizes of the spots and estimating the number of cell divisions involved, the frequency of the somatic mutations could be estimated. It was found that it was of the order of 267 per million cells both in gametogenesis and in the sepals. This rate was relatively constant in successive cell generations in different parts of the plant through four sexual generations. The lavender-alpha gene also mutates to purple, so that lavender-variegated plants give offspring which may be lavender-variegated, purple, and purple-lavender chimæras. This gene shows a high rate of mutability in early stages of development of the plant (since half the non-purple plants from seed are chimæras), relative stability in the early stages of sepal and petal development, and high mutability towards its end. The author concludes that these phenomena of variegation are not due to the gene being compound and composed of parts which segregate, but to a mutation which tends to occur in the particular gene at the time when it splits in mitosis.

Earthquakes and Mineral Springs.—The effect of earthquakes on mineral springs has often been noted. Mr. B. M. Radoslavoff traces the relations in Bulgaria as the result of the earthquake of 1928, in *Matériaux pour l'Étude des Calamités*, No. 25, 1931. The thermal springs are all in the neighbourhood of volcanic formations. Some springs dried up and several new ones appeared. The Meritchleri spring was replaced by exhalations of carbon dioxide. The Kovanlak springs ceased for three weeks and then began to reflow. Most of the well-known springs show an increased flow, in some cases as much as 200 per cent. The temperature of the different springs has, on the whole, remained unchanged, while in previous Bulgarian earthquakes the tendency seems to have been for temperatures to increase.

Soil Classification.—The possibilities of an international system for the classification of soils have recently been examined by L. L. Lee, of Rutgers University, the thesis appearing in the *Journal of South-Eastern Agricultural College*, Wye, Kent, 1931, with an extensive bibliography appended. The New Jersey system of classification is discussed at length, and the soils of the New Jersey (U.S.A.) area and of south-eastern England have been classified according to this system, enabling comparisons to be made. In both areas the soils occur in belted zones closely related to the geological formations, and in both cases also a direct relationship exists between the geological formation and climate and the distribution of the soil series, the number of soil classes being greater in central New Jersey. Podsolisation in general is further advanced in the soils of the American areas than is the case in south-eastern England. In both areas the importance of the parent geological materials is such that any system of classification applicable to both regions must be one in which geological factors are dominant, and it is suggested that the New Jersey system based on this foundation might find satisfactory application elsewhere in the British Empire and western Europe. Sandy profiles predominate in New Jersey, and heavy profiles, containing high percentages of silts and clays, in Kent, a direct relation existing between the texture of the soil profile and the geological formation in each district. Climate and soil reaction are also associated. No alkaline soils occur in the American area, whereas they are quite common in south-eastern England, climatic factors having altered the soil reaction more in the former than in the latter case.

A Photoelectric Relay.—The issue of the *Physikalische Zeitschrift* for Sept. 1 contains a note by Dr. L. Bergmann, of the University of Breslau, describing the arrangement he has devised for measuring small movements such as those of a galvanometer mirror by means of a relay depending on the sensitive selenium cell he described in the issue of the *Zeitschrift* for April 1. The cell consists of a thin layer of selenium in its conducting state, on an iron surface and covered by a semi-transparent film of gold or silver, deposited by cathode spluttering. In the relay a square of the cell of 1·5 cm. side is partially exposed, through a grating of ten parallel opaque strips, to light reflected from the mirror, the movement of which is to be measured. The incident beam forms on the grating an image of a similar grating, in such a way that a narrow strip of cell on one side of each strip of grating is illuminated, and motion of the mirror alters the width of this strip. The deflection of the galvanometer mirror in the cell circuit has by this arrangement been increased to 5000 times that of the mirror from which the reflection takes place.

Negative Ions.—Prof. H. D. Smyth has contributed an article to the July number of *Reviews of Modern Physics* upon the products and processes of ionisation by slow speed electrons. The principle of all the methods which have been employed is much the same; the gas is subject to a controlled source of ionisation, usually electrons, and the products are examined by one of the standard methods of magnetic analysis, or by the more recent electrostatic methods. Perhaps the most remarkable fact which emerges from this report is the scanty knowledge which we possess of the properties of negative ions. With a few exceptions, the usual statement which is made about any particular gas is that negative ions have been observed, but that practically nothing is known about the conditions governing their formation. Even in the case of the strongly electronegative substance iodine there is much uncertainty. I^-, I_2^-, and I_3^- occur in quantities comparable with those of the positive ions, but it is apparently as yet undecided what part is played by primary processes and what part by secondary processes in their formation. Perhaps the most significant observation is that to produce negative hydrogen atom ions by electron bombardment in water vapour, the electron energy has to be very closely either 6·6 volts or 8·8 volts; a similar law of formation is known for certain excited states of atoms, but is not found with positive ions.

Electrokinetics and the Interpretation of Surface Conductivity.—McBain and Du Bois, in the *Zeitschrift für Elektrochemie*, vol. 37, p. 651, point out that Helmholtz's theory of electroendosmose as due to the motion of the inner portion of the double layer should be replaced by the explanation put forward by McBain in 1924 and confirmed by experiments of Laing and others. The ions, water, and wall of the tube are all in motion relative to one another; the double layer is seldom complete, and the greater part of it plays no part in electrokinetics. All ions, walls, colloid particles, gels, diaphragms, etc., according to Laing, take part in the transport of current in the proportion of their actual conductivities, so that if μ is the total conductivity, the ion transport is of the form $c'u'/\mu$, where c = conductivity and u = mobility; and the wall, colloid, etc., transport is of the form $c_1 m_1 f_1/\mu$, where m_1 is the number of chemical equivalents carrying a faraday of charge and f the mobility. The formula of Smoluchowski has been disproved by experiments of McBain and Peaker on the increase in conductivity of solutions in contact with optically polished glass or quartz, and stearic acid on water: the results would give impossible values of the thickness of the electrical double layer. The classical formulæ of electrokinetics appear to be quite incorrect.

The British Heavy Steel Industry.

THE present position of the British heavy steel industry was reviewed by Prof. H. Stanley Jevons in a paper read on Sept. 30 to Section F (Economic Science and Statistics) of the British Association during the centenary meeting in London. Prof. Jevons said that the heavy steel industry is probably the weakest part of our industrial fabric at the present time, though it presents the greatest possibilities for development among the older British industries. The present depression is largely due to the effects of the War, as it has led to a 50 per cent increase in steel-making capacity, but the new plants erected during the War were erected at high costs and were not located or planned to the best advantage for peace-time operation. Since the War, production has remained stationary, and more recently has actually fallen off. Exports also have declined, but imports have increased somewhat. We are now surpassed by Germany as a steel-exporting country. Britain, however, is still pre-eminent in the production of high quality steels, and in this section of the industry Sheffield still leads the way. It is characteristic of the British steel industry, as of the other older British industries, that quality has been put first and low cost of production made entirely secondary.

German steelworks generally secure a larger output per hour with lower fuel consumption per ton, while their superior mechanical equipment reduces their costs of handling materials below those in British works. In Britain the cost of pig-iron is high, mainly on account of the small size of our furnaces. Wages also are somewhat higher than the rates paid in Germany and much higher than those in France and Belgium. This disparity might be counteracted by means of better equipment or improved business organisation, but so far this has not been achieved. The price policy adopted by the majority of firms in the British iron and steel industry is probably responsible for the high rate of unemployment, which has now risen to 43 per cent of those engaged in the industry. Even allowing for rebates given by British steel producers to contractors who regularly use British steel, imported steel is much cheaper than that produced at home. Thus, Belgian steel joists delivered in the Birmingham district are £4 6*s*. per ton and billets £3 16*s*., as against British prices of £8 and £5 per ton respectively. Prof. Jevons doubts if the rebate scheme is, on the whole, well advised, because it tends to limit the number of contractors employing British steel to those who agreed to the conditions of the rebate.

Among the various remedies which have been proposed as a cure for the post-War depression in the industry, the most prominent is the demand for a safeguarding duty. Foreign competition and severe unemployment in the industry can be advanced as arguments in favour of this policy, but, on the other hand, it might happen that a protective duty would merely bolster up inefficiency and might retard a necessary reorganisation of the industry. If a tariff is imposed, it will therefore be necessary to ensure that the industry will not raise home prices, but will only seek to work plants up to their capacity.

A committee appointed by the Government to investigate the condition of the industry recommended reorganisation on a regional basis, whereby heavy steel production would be concentrated in four districts. The committee considered that ten million pounds would be required to modernise existing plant. The Iron and Steel Trades Confederation—a trade union organisation—following to some extent the lead of this committee, proposed that a public utility corporation should be set up for the purpose of reorganisation on a regional basis.

Prof. Jevons pointed out that Britain was the first country to develop a great iron and steel industry, and, as compared with her competitors, she has still many valuable natural advantages, such as an abundant supply of coal. Moreover, these islands are peculiarly well situated for the export trade to all parts of the world. It is reasonable to expect a considerable growth in the demand for steel during the next twenty years if prices can be reduced, since steel is an essential requirement nowadays in the building industry, mining, railway wagon and carriage construction, and in many other industries. There is also a large potential export market in our colonies and undeveloped tropical dependencies.

Prof. Jevons recommends that the whole heavy steel industry in Britain should be replanned and rebuilt on a national scale with plants larger than any yet constructed in Europe. New plants of the latest type would have to be erected in South Wales, on the Clyde, on the north-east coast, and near Liverpool or London, with the view of facilitating the export trade. The industry should set itself to raise the annual production of steel from the present figure of about nine million tons and exports of four million tons to a total production of twenty-five million tons per annum, of which about ten million tons should be regarded as for export. This extension of the industry, though at first sight it might seem to be too ambitious a project, would make it no larger than the present size of the United States Steel Corporation. Prof. Jevons admits that the establishment of such an extensive reorganisation would require to be financed by the State, or at least interest on the capital would have to be guaranteed by the Government, but it is in the public interest to use the credit of the State in some manner to re-establish and enlarge the industry.

Applied Chemistry in Technical Colleges.

THE Board of Education has recently issued a report, prepared by H.M. Inspectors,[*] on the provision of instruction in applied chemistry in technical schools and colleges (except junior technical schools) in England and Wales which are in receipt of grants from the Board. It does not deal with instruction in universities. The survey has not been extended in an attempt to cover questions of provision and requirement wherever chemists are employed; the term 'applied chemistry' has been limited to the chief branches of chemical industry, which for this purpose is regarded as an industry in which raw material changes its composition as it passes through the works.

A table shows that more than 5500 students attended these courses; but the significance of the statistical information does not lie in the number of individuals receiving the instruction. A fact of greater importance is the wide adoption of the provision of well-balanced curricula instead of instruction in single and unrelated subjects. Many of the students who are not following such grouped courses are doing work of an advanced and sometimes post-graduate standard. Less than twenty per cent of the total number of students are receiving elementary instruction in single subjects, and a considerable proportion of these are attending lectures of a non-professional type and standard.

---

[*] Board of Education, Educational Pamphlets, No. 85 (Industry Series, No. 10): Report by H.M. Inspectors on the Provision of Instruction in Chemistry in Technical Schools and Colleges in England and Wales. Pp. 55. (London: H.M. Stationery Office.) 1*s*. net.

The report describes the general character and distribution of the facilities offered for the study in these institutions of applied chemistry, the information being grouped under the headings: fuel industries; chemical engineering and chemical technology; metallurgy; pottery and refractories; bleaching and dyeing; leather manufacture, rubber technology, and paper-making; foods and drugs; oils, fats, and waxes; painters' colours and varnishes; coal tar colours; synthetic resins and cellulose industries. While the tendency to defer the teaching of applied chemistry until an adequate knowledge of pure chemistry and ancillary subjects has been obtained is commended, it is stated that beyond the elementary stage the instruction provided in physics is rarely what is required—it is either too narrow or too wide. On the other hand, a few schools seek to meet the needs of a small number of students of varied requirements by offering lectures in certain subjects which all attend, the main differentiation being achieved by individual instruction in the laboratory. The wisdom of attempting such an "almost impossible task" is, however, doubted.

The attitude of employers has entered on a new phase, passing from individual benevolence to a clearly defined collective policy, and being associated with a closer interest, so that the training "is tending to become a definite element of industrial organisation". The position which has now arisen is that expanding knowledge renders necessary a higher standard of training, which can be given more satisfactorily and under less onerous conditions in part-time day courses than in classes held exclusively in the evenings. While the difficulty of interrupting routine work by releasing employees for this purpose is acknowledged, the wide adoption of such a plan by the engineering industry and other industries is quoted as an example which might with advantage be copied more frequently in applied chemistry. Not only is co-operation in the use of facilities desirable, but also the achievement of completely co-ordinated schemes of technical education is a matter which requires closer co-operation between educational administration and industry.

A relatively new problem is the provision of instruction suitable for men, engaged on plant or process, who control apparatus or machinery without sharing the chemist's responsibility or ambitions. The well-informed worker finds greater interest in his work, and renders more efficient service to his employer; but "the traditional method of approach is not likely to be successful. A new technique in teaching is required." Another type of instruction which seems desirable is the commercial training of men who are primarily chemists or technicians.

A Monument to Henri Moissan.

HENRI MOISSAN was born in Paris on Sept. 28, 1852, and died there, at the age of fifty-four, on Feb. 20, 1907. He is remembered to-day for his successful work on the isolation of fluorine, his experiments on the manufacture of artificial diamonds and the development of the electric furnace.

Moissan's isolation of fluorine in 1886 was accomplished by electrolysing a solution of potassium hydrogen fluoride in anhydrous hydrofluoric acid contained in a platinum tube. He was led to his researches on diamonds by the study of the allotropic modifications of carbon, and the minute diamonds he made were obtained by melting iron and carbon in a crucible and dropping the fused mass into water. The electric furnace which he used in these experiments consisted of a scooped-out block of marble, covered by a marble lid having two horizontal passages for the carbon electrodes, the current being obtained from a small dynamo.

Moissan's whole life was passed in Paris. He entered the laboratory of Fremy at the Muséum national d'Histoire naturelle at the age of twenty; at thirty-four he was appointed professor of toxicology in the École Supérieure de Pharmacie, in 1899 was transferred to the chair of mineral chemistry, and the following year became professor of general chemistry at the Sorbonne. Elected a member of the Paris Academy of Sciences in 1891, he was made a foreign member of the Royal Society and awarded the Davy Medal, and in 1906 received the Nobel Prize for chemistry. His son, Louis Moissan, an assistant at the École Supérieure de Pharmacie, who was killed in action on Aug. 10, 1914, left funds for founding prizes in memory of both his father and mother.

A fête in honour of Moissan was celebrated on Oct. 4, in brilliant autumn sunshine, in the cathedral town of Meaux, picturesquely situated on the banks of the Marne. The delegates were received on Saturday afternoon, Oct. 3, at the Ministry of Foreign Affairs on the Quai d'Orsay, and on the following morning nearly three hundred were taken by special train to Meaux to take part in the ceremonies there.

These ceremonies included the formal presentation to the Communal College (of which Moissan was a pupil from 1864 until 1870) of a plaque on the wall of the entrance hall, and in the afternoon the unveiling, by Mme. Jean Gerard, of a monument in a small square by the side of the town hall. The monument is in the form of an obelisk, from the upper part of which the rugged features of Moissan emerge from the solid stone, whilst on the side are sculptured diagrammatic representations of his electric furnace and of the apparatus with the help of which he isolated fluorine, with quotations from his own writings.

Discourses appropriate to the occasion were delivered, in a natural theatre formed by the surrounding buildings and gardens, under the direction of Prof. Behal, representing the Minister of Public Instruction. The first three discourses were by the president of the organising committee, by the mayor of Meaux, and by the president of the old students' association of the College of Meaux; the others were by M. Lebeau, the assistant and colleague of Moissan, representing the friends and students who had worked in Moissan's laboratory, by Prof. Honigschmid of Munich (himself an old student of Moissan) on behalf of the foreign delegates, and by Prof. Behal on behalf of the Government. Prof. Behal was supported by the presence, also in full dress, of his fellow academicians, Bertrand and Délépine, and by many of their French colleagues.

The list of foreign delegates included sixty-three names, but of those actually present the three representatives from Great Britain constituted as large a group as from any other country except Belgium and Italy. The ceremonies were associated with the eleventh meeting of the Société de Chimie industrielle, and owed much of their success to its vice-president, M. Jean Gerard, who has been responsible for the organisation of so many international gatherings.

Universal Decimal Classification.

THE fifth report of the International Committee on the Decimal Classification was presented by F. Donker Duyvis to the Tenth Conference of the Institut international de Bibliographie at the Hague on Aug. 25–29, and indicates the growing value and increasing use of the Universal Decimal Classification in the interchange of technical and scientific information. A translation of the chapter on electrotechnics has now appeared in Germany, and an extensive abridged manual of the classification is in preparation under the leadership of Dr. Günther. Further translations and expansions in progress in Germany were reported on by Herr C. Walther, the main interest being directed to the technical sciences, whereas in Great Britain progress has been mainly with the pure sciences, medical sciences, and agriculture. This lack of progress, as indicated by Mr. B. M. Headicar in a paper describing the construction of the "London Bibliography of the Social Sciences", is largely due to the absence of an English translation. Nevertheless, in meteorology, plant genetics, agriculture, and general biology, progress has been made, and Dr. J. G. Priestley in reviewing the position of bibliography in physiology indicated the value of the decimal system in constructing the complete card index of physiological and allied subjects which is a fundamental need. As a first step, *Physiological Abstracts* has already commenced to reprint decimal numbers from original papers in which they are used.

Many of the papers presented at the Conference afforded further evidence of the wide use of the decimal classification and the efforts being made to improve and extend the system by international co-operation. Its value in the organisation and documentation required for the *Révue générale de l'Électricité* was described by E. Beinet. O. Frank and C. Walther reviewed German developments in further detail, in which country it has been adopted by the German National Committee for the power and fuel bulletin initiated by the World Power Conference, and important libraries such as those of the Technical High School, Aachen, the I. G. Farbenindustrie A.-G, Leverkusen, the Central Technical Library, Frankfurt, the German Industrial Safety Museum, Berlin, the German Patent Office, and the Berufsgenossenschaft der Chemische Industrie, etc., while a full account of its use by the A.G. vormals Skodawerke in Pilsen was contributed by F. Kondelak.

In a report on "Documentation in Medicine" presented by Dr. Rene Sand, secretary of the League of Red Cross Societies, adoption of the decimal classification as a means of expediting the much-needed international co-operation in the organisation of documentation and bibliography in medicine was strongly urged, and the application of the decimal classification in the aluminium industry was discussed in a report presented by the S. A. pour l'Industrie de l'Aluminium à Neuheusen. A paper by J. Cenek described its use in industry in Czechoslovakia, and difficulties encountered by Polish engineers in adopting the system were described in a further paper from the Bibliographical Section of the Society of Polish Technicians, Varsovie. Other papers dealing with the decimal classification included J. Gevers' review of thirty years' experience with the system in the Belgian Patent Office, the application of the decimal system in local administration and social problems, and in public administration archives (L. Wouters), while G. A. A. de Voogd, chief of the Organisation Department of Bataafsche Petroleum Maatschappig, in a paper on rationalisation in documentary administration, described the extension of the decimal classification to meet the stringent demands of scientific management in the head office of a world-wide organisation.

Other papers presented at the Conference included one by Dr. M. Pflücke, principal editor of the *Chemisches Zentralblatt*, describing the organisation of abstracting and indexing of the *Chemisches Zentralblatt*, co-operation between libraries (J. W. Pafford), the standardisation of sizes (Frank), the use of addressographing machines with the decimal classification (W. Schümeyer), and international abstracting and indexing of scientific literature (Sir Frederic Nathan), and reports on the progress of the *Repertorium Technicum*, the *Index Bibliographicus*, and the Commission on Cataloguing Rules.

The Behaviour of Electrolytes in Solution.

A DISCUSSION on the influence of the medium on the properties of electrolytes initiated by Sir Harold Hartley on Sept. 24, in Section B (Chemistry) of the British Association during its centenary meeting in London, gained further interest from the presence of several distinguished foreign men of science whose investigations have largely contributed to recent developments in this field. Striking success has attended the application to dilute solutions of the Bjerrum hypothesis of complete ionisation. With the Debye treatment of the interionic forces, this has induced the extended study of other solvents with the object of testing the validity of the theory.

In the discussion, Prof. P. Debye described the results of experiments to determine the effect of alterations in frequency on the electrical conductivity of solutions in different solvents. This effect is due to the finite time (of the order of 10^{-7} sec.) which is required for the formation of an ionic atmosphere round an ion, and at very high frequencies or in very viscous media marked increases in conductivity can be obtained. For example, with a solution of calcium ferrocyanide in a mixture of 96 per cent glycerol and 4 per cent water, the conductivity is increased 500 per cent when a frequency of 10^4 cycles is employed. No values are obtained for the equivalent conductivity which are greater than the limiting value for infinite dilution, and this, according to Prof. Debye, implies that interionic forces are mainly operative.

Profs. N. J. Bjerrum and J. N. Brönsted discussed the solubilities of salts in different solvents and the agreement between experimental data and calculations based on Born's formula. Prof. Bjerrum, dealing with the forces between ions and solvent molecules in relation to the solubility of electrolytes, considers that the agreement is as good as can be expected on the basic assumptions made.

Evidence of the existence of strong specific forces between the ions and the solvent molecules was advanced by Sir Harold Hartley from the conductivity of salts in different solvents and by Prof. J. C. Philip from a comparative study of the nitriles as solvents. While in water and to a lesser degree in the alcohols simple univalent salts conform fairly closely with the requirements of the Debye-Onsager equation, in non-hydroxylic solvents, for example, acetone, nitromethane, and the nitriles, there are marked divergencies, which can most readily be interpreted by the assumption that the ions carry with them sheaths of solvent molecules. Dr. J. A. V. Butler has reached a similar conclusion from a study of the behaviour of electrolytes in mixed solvents, for example, alcohol-water mixtures, and showed that by the comparison of different properties conclusions can be drawn as to the nature of the molecules in contact with the ions. Dr. E. A. Guggenheim showed that this experimental evidence of ionic solvation is in agreement with theoretical requirements. Thus the dissociation constant of sodium chloride calculated by the methods of statistical mechanics is too small to account for the apparently complete dissociation of the salt in solution. If, however, hydration of the ions be postulated, a plausible value is obtained for the dissociation constant.

University and Educational Intelligence.

Oxford.—In his speech on the conclusion of his second year of office, the vice-chancellor (Dr. Homes Dudden, Master of Pembroke) explained why no election has yet been made to the vacant Savilian chair of astronomy. This, he said, is due to the fact that the whole problem of the future of astronomy in Oxford has been under review. A detailed scheme has now been prepared, which includes the construction of a new and thoroughly equipped observatory on a suitable site near Oxford; the representation of both positional astronomy and astrophysics on the professional staff; and an extension of facilities, in close connexion with the new observatory, for the teaching and study of meteorology and geophysics. The completion of the scheme is waiting for the provision of the necessary funds.

The University of Berne has conferred doctorates *honoris causa* on Sir Charles Sherrington, Waynflete professor of physiology in the University of Oxford, and Prof. Harvey Cushing, professor of surgery in Harvard University.

A special course of lectures on "Some Applications of Biochemistry to Modern Pharmaceutical Problems" will be given by Messrs. Frank Wokes and F. J. Dyer, in the Lecture Theatre of the Pharmaceutical Society of Great Britain, 17 Bloomsbury Square, on Oct. 22 and succeeding Thursdays, at 5.30 p.m. Admission to the first lecture is free without ticket. The subject will be "Physical and Chemical Conditions Necessary for Life".

The council of University College, Southampton, has appointed to the chair of engineering Wing Commander T. R. Cave-Browne-Cave, who was responsible for the machinery installation of the *R101*. Mr. H. Leech, who, with Wing Commander Cave, made every trial flight in the *R101*, and was lately foreman of the Engine Department at the Royal Airship Works, has been appointed experimental engineer.

Education in India cost in 1929, the latest year for which statistics have been published, 270 million rupees, of which nearly two-thirds was provided by government and local authorities. This expenditure has been frequently criticised, on the ground that it maintains a system of education appropriate enough for the small minority of pupils destined for employment in government and private offices and the learned professions, but quite unsuitable for the needs of the general population, which is mainly rural. In a pamphlet entitled "The Indian Education Problem: a Solution", Mr. J. C. Ghosh, principal of the School of Chemical Technology, Calcutta, sketches an alternative system designed to divert a due proportion of educational effort into channels tending to improvement of agricultural and manufacturing industries and the public health. In the forefront of his suggestions is a plan for rural education on practical lines by teachers who would be maintained by the well-to-do villagers in rotation, "according to traditional custom and hospitality". In urban areas, boys and girls would start their education at home in conjunction with manual labour "in ancestral or family occupation", municipal and other free primary schools being maintained only for the children of parents too poor to undertake this home training. All pupils up to fourteen years of age would be scouts, and their efficiency in scouting, literacy, manual and physical training would be tested in camps of exercise, the existing expensive system of formal inspections being abolished. Literary education in secondary schools and universities would be ordinarily restricted to the rich and to exceptionally gifted boys and girls.

Birthdays and Research Centres.

Oct. 20, 1862.—Prof. Thomas H. Bryce, F.R.S., regius professor of anatomy in the University of Glasgow.

The chief investigations in progress in my laboratory are: first, it is impossible in some cases to reach decisive interpretations—by ordinary methods of investigation—of the appearances seen in serial sections of the free mammalian blastocyst just before implantation. A special technique is therefore being developed by Dr. Maclaren for the observation of the living blastocyst and for recording the results. Some success has already been obtained. Second, it was discovered by Dr. Nicol that in the intravitam staining of the tissues by trypan blue, the uterine mucosa (in *Cavia*) at certain stages was densely stained, due to the accumulation of certain cells packed with blue granules. This has been followed up, suggestive results are being obtained, and an interesting line of research is opened.

Oct. 20, 1891.—Dr. James Chadwick, F.R.S., fellow of Gonville and Caius College, and assistant director of radioactive research, Cavendish Laboratory, Cambridge.

I am studying, with the help of collaborators, the effects of bombarding elements by α-particles, in particular, the emission of protons and γ-radiations from the atomic nuclei and the scattering of the α-particles. The wave mechanics has given a clearer view of these problems, and the application of new experimental methods is giving new and detailed information. I hope that in a short time we shall be able to describe completely the interaction between an α-particle and an atomic nucleus, and have a reasonable picture of the structure of the nuclei of some elements.

Oct. 22, 1876.—Prof. Harold Hilton, professor of mathematics, Bedford College, University of London.

At the request of the Clarendon Press, I have been engaged lately in the preparation of a second edition of my book on "Plane Algebraic Curves". Time not absorbed by this task and the duties of my professorial work is mainly devoted to the study of problems in affine and projective differential geometry.

Societies and Academies.

Paris.

Academy of Sciences, Aug. 24.—**Georges Giraud**: Extension of the notion of principal elementary solution and applications.—**G. Nadjakoff**: The capacity of the quadrant electrometer.—**Adolfo T. Williams**: Ultimate lines and absorption lines. Absorption lines are not all ultimate lines, and very few of the latter are absorption lines.—**Norbert Casteret**: The communication of the Trou du Toro with the Goueils de Jouéou, the source of the Garonne. The Trou du Toro and the Goueils de Jouéou communicate. The underground flow, as shown by fluorescin used in large amounts, is very rapid, 400 metres per hour. The negative results obtained by E. Belloc in 1896–1900 were due to the fact that the dye was added in insufficient quantities.—**J. Bougault** and **G. Schuster**: The composition of karité butter. By the application of Hilditch's method of oxidation by potassium permanganate in alkaline solution, it was shown that karité butter contains 7·3 per cent of saturated glycerides, the unsaturated glycerides representing 92·7 per cent.—**Maurice Nicloux**: The combustion of alcohol by the pœcilotherm: the value of the temperature quotient. An account of experiments on the combustion of alcohol in the frog at temperatures ranging between 1° C. and 29° C. Within these temperature limits the quantity of alcohol burnt in 24 hours varied from 14 to 97 per cent of the amount injected. The temperature quotient of the biochemical reaction equals 2.—**Georges Bourguignon**: The technique of the measurement of large chronaxies, 0·3 to 1·5 sec.—**J. E. Abelous** and **R. Argaud**: The formation of adrenaline in the suprarenal gland. It is generally held that adrenaline is formed exclusively in the medullary substance; the small amounts found in the cortical substance have been regarded as due either to post-mortem diffusion or to the presence of stray islands of medullary substance. The author's experiments contradict this view, and show that the elaboration of adrenaline takes place in the cortical substance.—**Léon Velluz**: The antitoxic properties of certain diphenols and their mode of action.—**Georges Blanc** and **J. Caminopetros**: The sensibility of the spermophil (*Citillus citillus*) to the virus of exanthematic fever.

Aug. 31.—The president announced the death of Jean Effront, *correspondant* for the section of rural economy.—**H. Douvillé**: A curious meteorological phenomenon. A description of a form of globular lightning producing mechanical effects but showing no sign of electrical action.—**E. Bataillon** and **Tchou Su**: Activation, the elimination of a polar globule, and polyvoltinism in the *Bombyx* of the mulberry tree.—**Paul Delens**: The projective geometry of congruences of curves.—**E. Kogbetliantz**: The series of Hermite and of Laguerre.—**G. Kolossoff**: An application of the formulæ of Schwarz, Villat, and Dini to a plane problem of elasticity.—**Tournayre**: The calculation of secondary ribs in reinforced concrete.—**Ch. Bertin**: The determination of the point by radiogoniometry.—**J. Fallou**: The transmission of polyphase high frequency currents along cables for the transport of energy and the selective protection of electric networks.—**L. Hackspill** and **R. Lauffenburger**: The action of heat on the alkaline diacid phosphates. The salts studied ($NaH_2(PO_4)2H_2O$, $Na_2H_2P_2O_7 . 6H_2O$, $LiH_2(PO_4)$, $KHPO_4$, $K_2H_2P_2O_7$) lose water of crystallisation in a vacuum at well defined temperatures. The dehydration of ortho into metaphosphate generally takes place with intermediate formation of pyrophosphate, and in certain cases through tetraphosphate. — **André Meyer** and **Robert Vittenet**: The homophthalimides substituted in the nitrogen by aromatic radicals.—**Louis Bounoure**: The existence of a germinal determinant in the undivided egg of the russet frog.—**C. Levaditi** and **P. Lépine**: The study of 45 elements from the point of view of their curative properties in spirilloses, syphilis, and the trypanosomiases. Only 10 of the 45 elements studied have therapeutic properties as regards such diseases.

Cape Town.

Royal Society of South Africa, July 15.—**W. Pugh**: The influence of fluoride ions upon the reduction of potassium permanganate. (1) Reduction with antimonious salts. In an attempt to overcome the difficulty of the fading of the end point in the estimation of antimony by the permanganate method, the effect of potassium fluoride was investigated. The consumption of permanganate increased by 25 per cent, and the solutions developed colours characteristic of manganic ion. The end point was, however, sharply distinguishable.—**P. R. v. d. R. Copeman** and **F. J. Dillman**: Decomposition of guano. During storage in an air-dry condition there is a loss of total nitrogen due to the loss of ammonia from guano. In a moist condition the uric acid in guano becomes converted into ammonium compounds and on subsequent drying there is an increased loss of nitrogen.—**A. C. Leeman**: The antimony electrode as a means for *p*H measurements. The antimony electrode was tested on various buffers and soil solutions under controllable temperature conditions. It has been found that the potentials are not reproducible, showing a constant drift and extraordinary differences in potential when the same liquid is tested on different days.

Geneva.

Society of Physics and Natural History, June 4.—**Georges Tiercy**: The variation of the radial velocity of U Aquilæ. The author has employed an indirect method of determining the curve of radial velocities of the star U Aquilæ. He compares the result obtained with that given by the Mount Wilson Observatory obtained from direct measurement of spectrograms.—**R. Wavre**: (1) The theory of potential. The author shows that two distinct bodies having the connexion of the massive sphere cannot create the same potential, either round a point common to them if they have a small portion of common surface, or at any point in space if they are separated.—(2) Small vibrations of fluid stars. The author shows that the uniform method for research on the planetary figures applies also to stars which alter their shape in course of time; he applies it in particular to small movements and to the phenomena of tides on a perfectly fluid star.

Leningrad.

Academy of Sciences, *Comptes Rendus*, 1931, No. 4.—**B. Gerasimovic**: Probability theorems connected with the discovery of variable stars by a photographic method. Formulæ are given for cepheids and long-period variables, for eclipsing variables and for the probable number of variables in the field.—**V. Barovskii**: Description of a new species of the genus *Malthodes* Kiesw. (Coleoptera, Cantharididæ). *Malthodes kiritchenkoi* sp. n. is described from the Ussuri province.—**G. Nadson** and **G. Burgwitz**: Yeasts from the North Polar ocean. Yeasts belonging to the genus *Torula* have been found on the surface of sea-weeds *Laminaria saccharina*, *Alaria esculenta*, *Fucus vesicolosus* and *Rhodymenia palmata*. The yeasts can develop at the temperature of 2°-4° C. The addition to the nutritive medium of 3 per cent of salt from the sea water depressed the intensity of the development of the yeasts. This suggests that the marine yeasts originated on land and only adapted themselves to life in sea.—**A. Krylov**: One of the main causes of the loss of airships *R* 38, *R* 101, and others. The author believes that the reason for airships breaking across the middle is the insufficient area of the rudder, which is therefore unable to withstand lateral forces when turning.—**A. Fersman**: A new law on the composition of granitic pegmatites. Pegmatite processes may be regarded as a series of systems in equilibrium subjected to fundamental physico-chemical laws. Pegmatite solutions must be considered as closed systems.

MELBOURNE.

Royal Society of Victoria, July 9.—L. A. Thomas: The readvancement of the vegetation over the mined areas of Bendigo.—**F. Chapman and Irene Crespin**: New species of *Lepidocyclina*, *L. hamiltonensis* and *L. howchini*, are described from a bore at Hamilton, Western Victoria. Other species hitherto found only in the East Indies, namely, *Lepidocyclina martini* and *L. radiata*, are illustrated from bores at Hamilton and Gippsland. *L. sumatrensis* var. *mirabilis*, lately described from the island of Formosa, is recorded from the Lower Miocene of Victoria. *Miogypsina mamillata* and *M. saitoi*, recently described from Formosa, are illustrated from borings and outcrops at Matapau, New Guinea.—**F. Chapman**: Two new Australian fossil king-crabs.—These belong to the orders Xiphosura and Synxiphosura respectively. *Pincombella belmontensis*, gen. et sp. nov., is a small though interesting predecessor of the living king-crabs and allied to the Carboniferous genus *Belinurus*; it was discovered at Belmont, Newcastle, N.S. Wales, and is of Permian age. The second form, *Hemiaspis tunnecliffei*, is related to one of the four species hitherto known from the Silurian of Scotland.

ROME.

Royal National Academy of the Lincei, March 15.—U. Cisotti: Determination of the function of a regular complex variable in a known circular corona: the real part on the external circumference and the imaginary part on the interior.—**M. La Rosa**: New proof of the influence of motion of the source on the velocity of light: ballistic explanation of Miss Leavitt's law (1).—**L. Cambi and A. Gagnasso**: Cobalt nitrosodithiocarbamates. In aqueous or aqueous-alcoholic suspension, and in absence of air, cobaltous dithiocarbamates actively absorb nitric oxide with formation of complexes of the type $[(R_2N.CS_2)Co.NO]$, which are in all respects analogous to those of iron. The nitroso -*N*:*N*-dimethyldithiocarbamate and the nitroso -*N*-piperidyldithiocarbamate are described.—**F. Tricomi**: The distribution of the baricentres of plane sections of a body.—**T. Boggio**: Laplace's operator and equations of elasticity in curved spaces.—**R. Calapso**: Wilczynski's prime directrix and problems connected therewith.—**Ugo Broggi**: The integration of linear equations to the differences with constant coefficients.—**G. Racah**: Characteristics of Dirac's equations and the principle of indetermination.—**Angelina Cabras**: The expression of the work in generalised spaces.—**G. A. Barbieri**: Contribution to the knowledge of rhodium compounds. The preparation and properties of a number of rhodiothiocyanates and rhodiocyanides are described.—**M. Airoldi**: Certain fossil Corallinaceæ of the Canaries.—**Amelia Tonon**: The structure of buds of the mulberry and their development.

Diary of Societies.

FRIDAY, OCTOBER 16.

PHYSICAL SOCIETY (at Imperial College of Science), at 5.—G. A. Wedgwood: Young's Modulus for Steel in Two Directions in a Bar.—Dr. N. W. McLachlan: On the Effective Mass of Flexible Discs and Conical Diaphragms used for Sound Reproduction.—A. T. McKay: Further Study of Diffusion for the Infinite Plane Sheet.—Miss Theresa Dillon and Miss C. Lovett: Demonstration of the Effects of Mechanical Disturbance on a Neon Lamp.

HISTORICAL ASSOCIATION (at 22 Russell Square), at 5.30.—Sir Bernard Pares: Russia since the War.

INSTITUTION OF MECHANICAL ENGINEERS (Special General Meeting), at 6.—Approval of Draft By-Laws.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Annual General Meeting) (at Literary and Philosophical Society, Newcastle-upon-Tyne), at 6.—J McGovern: Presidential Address.

SOCIETY OF DYERS AND COLOURISTS (Manchester Section) (at 36 George Street, Manchester), at 7.—Dr. A. F. Kertess: The Chemical Development of Modern Textile Finishing Products.

WEST OF SCOTLAND IRON AND STEEL INSTITUTE (at Royal Technical College, Glasgow), at 7.15.—J. Bird: Presidential Address.

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (jointly with Institute of Chemistry) (at Thomas' Café, Swansea), at 7.30.—C. M. W. Grieb and R. H. Jones: The Influence of Sulphur Compounds on the Extraction of Nickel by the Carbonyl Process (Lecture).

BRITISH ELECTRICAL DEVELOPMENT ASSOCIATION (at Royal Society of Arts), at 7.30.—Dr. W. Beaumont: Light Therapy, with particular reference to Ultra-Violet Irradiation.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—C. C. Berger: The Characteristics of Commercially Pure Iron.

NELSON TEXTILE SOCIETY (at Nelson Technical College), at 7.30.—J. Loxham: Wonderful Products from Coal.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology, Medicine, and Psychiatry Sections), at 8.15.—Discussion on Medical Indications for Premature Termination of Pregnancy.

Royal Society of Medicine (Physical Medicine and Radiology Sections), at 8.30.—Dr. F. G. Thomson and Prof. W. Morison: Presidential Addresses.

SATURDAY, October 17.

Institution of Municipal and County Engineers (Southern District) (at Municipal Buildings, Newbury), at 11.15.

Institute of British Foundrymen (Lancashire Branch, Burnley Section) (at Technical School, Accrington), at 6.30.—F. J. Cook: Cylinders, for Steam, Diesels, and Compressors.

MONDAY, October 19.

Genetical Society (at Linnean Society), at 3.30.—Dr. C. B. Bridges: Genic Balance and Related Problems.

Royal College of Physicians of London, at 4.—Dr. R. Hutchison: Harveian Oration.

Institution of Electrical Engineers (Mersey and North Wales (Liverpool) Centre) (at Liverpool University), at 7.—P. M. Hogg: Chairman's Address.

Institute of Brewing (London Section) (at First Avenue Hotel).—T. R. Dixon: Acids as Enzymic Activators in Malt and their Effect on Mashing Operations.

TUESDAY, October 20.

Royal Society of Medicine, at 5.30.—General Meeting.

Zoological Society of London, at 5.30.—Secretary: Report on the Additions to the Society's Menagerie during the months of May, June, July, August, and September 1931.—S. L. Hora: Biological Notes on a Loricariid Fish from Brazil in the Society's Aquarium.—Dr. Ida Mann: Iris Pattern in the Vertebrates.—Margaret H. Fullarton: Notes on the Respiration of the Lungfish, *Lepidosiren*.—A. G. Lowndes: A Small Collection of Entomostraca from Uganda collected by Mr. G. L. R. Hancock.—V. V. Hickman: A New Family of Spiders.—G. Jennison: Cobras bred at Belle Vue Zoological Gardens, Manchester.

Institute of Fuel (at Institution of Mechanical Engineers), at 6.—Sir Hugo Hirst, Bart.: Presidential Address.—B. Pochobradsky: Selected Problems relative to the Coal Industry.

Institute of Transport (at Institution of Electrical Engineers), at 6.—H. W. Payne: Some Present Limitations in the Transport of Freight Traffic by Railway, with Suggestions.

Illuminating Engineering Society (at Lighting Service Bureau, 15 Savoy Street), at 6.30.—Report on Progress in Illuminating Engineering; Exhibits of Photometric Apparatus, Novel Lighting Fittings, etc.

London Natural History Society (at London School of Hygiene and Tropical Medicine), at 6.30.—Dr. G. Carmichael Low: Some Structural Observations on the Waders (*Scolopacidæ*) and their Bearings on the Classification of the Family.

Institution of Electrical Engineers (North-Western Centre) (at Midland Hotel, Manchester), at 7.—L. Romero: Chairman's Address.

Institution of Electrical Engineers (Scottish Centre) (at 39 Elmbank Crescent, Glasgow), at 7.30.—Prof. G. W. O. Howe: Chairman's Address.

Iron and Steel Institute (jointly with Sheffield Metallurgical Association) (at Sheffield Metallurgical Club, Sheffield), at 7.30.—J. H. Andrew, W. R. Maddocks, D. Howat, and E. A. Fowler: Equilibrium of Certain Non-Metallic Systems.—W. H. Cunningham and J. S. Ashbury: Surface Hardening by Nitrogen of Special Aluminium-Chromium-Molybdenum Steels on a Production Basis.—G. A. Hankins and M. L. Becker: Effect of Surface Conditions produced by Heat Treatment on the Fatigue Resistance of Spring Steels.—B. Matuschka: Solidification and Crystallisation of Steel Ingots: The Influence of the Casting Temperature and the Undercooling Capacity of the Steel.

Royal Aeronautical Society (Bristol Branch) (at Bristol).—E. G. Gordon England: Soaring Flight; its Function in Aviation.

Institute of Brewing (Scottish Section) (at Caledonian Hotel, Edinburgh).—G. H. Gemmell and R. G. Thin: Some Notes on Water Analysis.

WEDNESDAY, October 21.

Royal Microscopical Society (at B.M.A. House, Tavistock Square), at 5.30.—Dr. R. S. Clay and T. H. Court: Some Early Achromatic Microscopes—Fraunhofer's Microscopes.—Dr. G. M. Findlay: Virus Inclusions in Mice Livers.

Iron and Steel Institute (jointly with Manchester Metallurgical Society) (at Engineers' Club, Manchester), at 7.—G. A. Hankins and M. L. Becker: Effect of Surface Conditions produced by Heat Treatment on the Fatigue Resistance of Spring Steels.—Prof. F. C. Thompson and R. Willows: A Critical Study of the Origin of the Banded Structure of a Hot-worked Hypo-eutectoid Steel.

Institution of Production Engineers (Birmingham Section) (at Grand Hotel, Birmingham), at 7.—T. G. Heckles: Control of Factory Production.

Institution of Electrical Engineers (Sheffield Sub-Centre) (at Royal Victoria Hotel, Sheffield), at 7.30.—I. Scott Mackenzie: Chairman's Address.

Folk-Lore Society (at Cecil Sharp House, 2 Regent's Park Road), at 8.—Miss Maud Karpeles: English Folk Dances, their Survival and Revival (with Illustrations by members of the English Folk Dance Society).

St. Paul's Ecclesiological Society (at Royal Institute of British Architects), at 8.—N. H. Baynes: The Sacred Picture in the Greek Church.

Society of Glass Technology (at Science Museum), at 8.—E. Meigh: The Future of Glass Melting (Presidential Inaugural Address).

THURSDAY, October 22.

Society of Glass Technology (at Science Museum), at 4.45.—Prof. W. E. S. Turner: Modern Artistic Glass (Lecture).

Linnean Society of London, at 5.—P. R. Lowe: Exhibit illustrating Structural Diversity in Charadriine Genera Correlated with Similarity of Colour-pattern.—S. H. Lele: The Circulation of Blood in the Air-breathing Chambers of *Ophiocephalus punctatus* Bloch.—Rev. H. J. Riddelsdell: Exhibit of Dried Specimens of the Yellow-flowered Privet.—Dr. L. Cockayne and Dr. W. A. Sledge: A Study of the Changes Following the Removal of Subalpine Forest in the Vicinity of Arthur's Pass, Southern Alps, New Zealand.

Child-Study Society (at Royal Sanitary Institute), at 6.—Dr. A. F. Tredgold: Some Observations on Mental Development (Cockburn Memorial Lecture).

Institution of Electrical Engineers, at 6.—Capt. J. M. Donaldson: Presidential Inaugural Address.

Institute of Marine Engineers (jointly with other Societies) (at Institution of Mechanical Engineers), at 6.—A. Bjorklund: Marine Reciprocating Steam Plants: Some Outstanding Factors of Economy.

Institute of Metals (Birmingham Local Section) (at Birmingham University), at 7.—Sir William Larke: Inaugural Address.

Royal Aeronautical Society (Gloucester and Cheltenham Branch).—Nickel and its Alloys (Lecture).

FRIDAY, October 23.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Specimens illustrating the Nature and Extent of the Changes which have Affected the Jaws of English People in Recent Centuries.

Institution of Mechanical Engineers, at 6.—Lt.-Col. E. Kitson Clark: Presidential Address.

Junior Institution of Engineers, at 7.30.—I. Fagelston: Some Instruments used in connexion with Power Plant.

Royal Society of Medicine (Epidemiology and State Medicine Section), at 8.—Prof. Major Greenwood: The General Register Office (Presidential Address).

Royal Aeronautical Society (at Merchant Taylors' School).—C. R. Fairey: Lecture.

PUBLIC LECTURES.

FRIDAY, October 16.

University College, at 5.—Dr. L. E. Bayliss: The Respiratory Functions of the Blood. (Succeeding Lectures on Oct. 23 and 30 and Nov. 6.)

Institution of Electrical Engineers, at 5.30.—E. C. Crittenden: The Measurement of Light: its Basis and its Significance. (Succeeding Lectures on Oct. 21, 23, 26, and 28.)

SATURDAY, October 17.

Royal Institute of British Architects, at 3.—H. S. Goodhart-Rendel: Some Opinions upon Furniture and Decoration.

Horniman Museum (Forest Hill), at 3.30.—H. N. Milligan: Success and Failure in the Animal World.

MONDAY, October 19

London School of Economics, at 5.—Prof. P. Denis: Some Geographical Problems in South America. (Succeeding Lectures on Oct. 20 and 21.)

University College, at 5.15.—Prof. F. Tobler: The Development of the Organism of Lichens: An Introduction to General Lichenology. (Succeeding Lectures on Oct. 20 and 22.)—At 5.30.—Prof. F. W. Thomas: Kings and Emperors of Ancient India.

University of Leeds, at 8.—Prof. J. W. Cobb: The Kitchen Grate.

TUESDAY, October 20.

University of Leeds, at 5.—Prof. T. T. Read: The Rôle of Dentistry in Preventive Medicine.

King's College, London, at 5.30.—Sir Bernard Pares: Russian History to 1861: Kiev and the Water Road.

Gresham College, at 6.—W. H. Wagstaff: Geometry. (Succeeding Lecturers on Oct. 21, 22, and 23.)

WEDNESDAY, October 21.

Royal Institute of Public Health, at 4.—Sir Leonard Hill: Light and Air and the Health of the Citizen.

London School of Hygiene and Tropical Medicine, at 5.—Lt.-Col. G. E. F. Stammers: Tropical Hygiene. (Succeeding Lectures until Oct. 30.)

Armstrong College (Newcastle-upon-Tyne), at 5.30.—Prof. Irvine Masson: Problems in the Teaching of Science (Alexander Pedler Lecture).

THURSDAY, October 22.

King's College, London, at 5.30.—Dr. Eveline Martin: West Africa of To-day: Southern Nigeria: the Country, the People, and some Education Problems.

Pharmaceutical Society of Great Britain, at 5.30.—F. Wokes and F. J. Dyer: Some Applications of Bio-chemistry to Modern Pharmaceutical Problems.

SATURDAY, October 24.

Royal Institute of British Architects, at 3.—A. S. G. Butler: Tendencies in Modern Buildings.

Horniman Museum (Forest Hill), at 3.30.—F. A. Rudd: The Legacy of Antiquity.

EXHIBITION.

October 21 to December 31.

Exhibition of Modern Technical and Artistic Glasses (at Science Museum, South Kensington). (Formal opening by Sir Richard Gregory, Bart., on Wednesday, Oct. 21, at 4.)

ANNUAL MEETING.

October 31 to November 2.

International Society of Medical Hydrology (at American Hotel, Amsterdam).—Discussions on the Influence of Chill in the Causation of Disease, opened by Profs. Schade and van Loghem, and on Factors in Marine Treatment, opened by Prof. Moll and Dr. Haberlin.

No. 3234, Vol. 128]

Native Administration in Africa.

DURING the past few years, incidents have occurred from time to time in certain parts of the British Empire which suggest that British administrators are losing their hold on the minds, if not the affections, of the indigenous races of the tropics. There can be no doubt that, if greater insight into the feelings and prejudices of the native races had been shown, recent difficulties in India, Burma, and East and West Africa would not have arisen, or would never have reached such an acute stage. There is no excuse for this state of affairs so far as our relations with the African Negro are concerned, since as a rule he started with a great admiration and friendliness for the European, while the workings of his mind are atune to ours and run to a large extent on parallel lines.

It is a truism to say that no people can be efficiently ruled and influenced without sympathy and that true sympathy cannot be given without a more than superficial knowledge of their religious beliefs and old customs. This point was emphasised by Lord Lugard in his recent lecture before Sections E and H of the British Association, an account of which appears elsewhere in this issue. Yet it is still insufficiently grasped by the British people as a whole, and even by those who are engaged in colonial administration. To this must be ascribed very largely the growing dissatisfaction and unrest which have been so evident of late years.

Take, for example, Nigeria, one of the greatest possessions of the British Crown and of immense economic value to the whole world, both from the number (some 20,000,000) and the industrious character of its population and from the great natural resources of the land. There is probably no country where a knowledge of the beliefs and customs of the people is of such paramount importance, and none where the study of these matters has received less consideration. The unhappy change which has there taken place in the feelings of the natives towards the administration, has been to a certain extent brought about by unavoidable causes, such as the world disturbances due to the War and the consequent trade depression; a misunderstanding of the phrase self-government; the departure of a large number of the older and more experienced officers and their replacement by young men (cadets now go out at the age of about twenty-two) of no experience and perhaps of greater inclination to hasty action; and the rapid spread of motor communications, which encourages officials to remain more in central towns and to confine their travelling to quick journeys in cars along the main roads, instead of, as in the old days, going slowly from place to place on foot or by bicycle, visiting even the smallest villages and getting to know the people thoroughly.

The chief cause of dissatisfaction in Southern Nigeria, however, has undoubtedly been the methods employed in the introduction of taxation, which has occupied so large a part of the officials' time since 1926. Unfortunately, the preliminaries for this momentous step were entrusted to officers with little experience of the country or acquaintance with the people. Those who had studied these matters and ventured to suggest the desirability of a longer preparation and further investigation were disregarded. The affair culminated, most regrettably, in the serious riots which took place at the end of 1929, and the old mutual confidence between the administrative officers and the mass of the people is now largely at an end.

It is true that, under the ægis of Sir Hugh Clifford, who was himself interested in native customs, a section on anthropology was included in the 1921 Census reports, and that, since then, two officers have been entirely engaged in anthropological studies ; little consideration, however, seems to have been given to this in the framing of government policy—though, on the Gold Coast, Capt. Rattray's illuminating investigations into the comparatively small but important Ashanti tribe met with considerable encouragement and attention.

During the last decade much stress has been laid on the necessity of learning native languages. This is all to the good, even in the southern provinces of Nigeria, where there are scores of languages and the main three are divided into so many dialects that it is difficult for an officer to become really proficient in any one of them, unless he is always stationed in the same place, which is rarely possible or desirable. The number of Europeans who could give a translation accurate enough for court purposes is very small indeed, while the African is such a remarkable linguist that, as a rule, he acquires a better mastery of English than the average European can hope to do of his tongue. English is being learned throughout Southern Nigeria so quickly that in a few years it will be the lingua franca of the whole country, a position which it has already attained on the main roads. Even so, it is very advantageous for an officer to acquire some knowledge of as many languages as possible so that he can to a certain extent check his interpreter, although this may be best achieved by care in the framing of questions ; it is generally easy to tell from the answers if these, or the statement, have been correctly translated. It is, however, of far greater importance to become conversant with the religion and customs of the people. It is not yet appreciated how largely the Negro is ruled by his religious feelings. His belief in the spiritual world is no 'accident', to be thought of occasionally and then dismissed from the mind, but forms the essence of his being ; he has, for example, to take into consideration the dead as well as the living members of his family. This information can be gained if sought with sympathy and tact and if the few more or less technical words are learned and defined.

It is probably to the new situation created by the taxation troubles, which came to the knowledge of the Secretary of State, that we owe the recent change in the attitude of the Nigerian Government indicated by the publication of three substantial volumes of ethnographical investigations ; it is to be hoped that government efforts in this direction will not cease here, even in the present straitened financial circumstances. The stress laid by Lord Passfield on the importance of anthropology has at last made clear the necessity for the study of this science. As a result, officers are now being encouraged to inquire into the indigenous social organisation before any further steps are undertaken in the way of native administration schemes.

Here, however, another danger has arisen which should be guarded against, since the inquiries have generally been made by junior officers of little experience and training. This gives rise to mistakes, and it is essential that no further changes in administration should be introduced unless all such investigations are carefully checked by men with full knowledge of the country and people—particularly as regards the native courts. The native courts have been the means of providing a very fine system of justice, despite abuses in the way of bribes (partly a relic of the old custom of both sides giving presents to the judges) and pressure by court officials, especially of late years, during which they have not been so closely supervised.

The courts are composed of the chiefs of the various villages and are only an extension of the old indigenous gerontocracies. Fortunately, native law and custom were on the whole fair and reasonable and are still in force except in such matters as witchcraft, where they conflict with European ideas. There are no legal quibbles, and there is no doubt that the common people obtain a greater degree of justice than in those courts which are under indirect rule and the influence of powerful emirs and kings. Bribery was largely checked and a general improvement shown in one province where two reforms were instituted: first, every member is allowed to sit and give judgment at each session, instead of only three or four chiefs in rotation; and secondly, the members take an oath on the strongest local juju to give a just decision—though this would only have effect in areas where the belief in jujus is still strong.

The people themselves would, on the whole, prefer to have their cases tried by the administrative officers—especially in those parts where bribery is much practised—but this is rendered impossible by the immense number of cases, even if it were not desirable that they should gradually develop their institutions in the direction of self-government. A large amount of executive power is also entrusted to the native courts, and, as a matter of fact, the greater part of the administration of the southern provinces is carried on by their means.

In the present state of affairs, the absolute necessity of paying more attention to the study of anthropology cannot be too strongly emphasised. The tropical colonies of the British Empire are vital to its existence, and there is grave danger that these will pass out of its control unless science is brought to bear in their administration.

(2) *The British Association for the Advancement of Science: a Retrospect, 1831–1931.* By O. J. R. Howarth. Centenary (second) edition. Pp. vii + 330 + 19 plates. 3*s*. 6*d*.

(London: British Association, 1931.)

THE object of the British Association is, and always has been, the advancement of science. By means of its annual meetings at home and in the Dominions, by financial help towards scientific research, and by the printed reports of its yearly assemblies, it has acted as a leaven in the intellectual life of our nation. Now, in its centenary year, it has published two handbooks giving further justification for its honourable and useful existence. The pair are really companion books. The latter work traces the birth, growth, and struggle for recognition in a conservative age—and the subsequent triumph—of the British Association, which has roamed from county to county, and from continent to continent, dispensing its good offices in the promotion of science. This official "Retrospect" has been compiled by Mr. O. J. R. Howarth, the secretary of the Association, and the task of collecting the material and welding it into a coherent, readable mass of information has been well performed.

From this record of the nomadic life of the Association, the first edition of which was reviewed in Nature of Sept. 2, 1922, we turn, perhaps in undue haste, to the story of "London and the Advancement of Science", written by various authors, under the general editorship of Mr. Howarth.

The book originated in a suggestion made by Dr. Allan Ferguson, which was given effect by the Council of the British Association. It contains ten chapters dealing with the learned societies, the education of London, the development of medicine, government and scientific research, and such familiar features of the metropolis as the museums, Kew Gardens, and the Royal Observatory at Greenwich. A brief history of the scientific instrument makers of London concludes the book.

Dr. Ferguson's introductory survey of the outstanding names of London men of science who may be considered the most worthy of mention in such an extended scroll, provides a foretaste of good things to come. He relates the fact, not generally known, that Chaucer was an accomplished astronomer and the author of a treatise on the astrolabe, for a long time a standard work of reference. The other names selected are those of Henry Billingsley, the first translator of Euclid into English, a Lord Mayor who lived in Candlewick Ward—a modified designation of his residential quarter persisting in the name of Cannon Street; William Gilbert, the author of "De Magnete", of whose scientific spirit and achievements Galileo had the greatest esteem; William Harvey the physician, Francis Bacon, Christopher Wren, Henry Cavendish, and William Hyde Wollaston. One other figure is among those narrated in great detail, namely, John Hill, "botanist, apothecary, physician, hackwriter, actor, and playwright". A fairly good case is made out for this man's inclusion in such distinguished company, for, in spite of his mental vagaries and diffuse occupations, "his judgments on specific points were well in advance of his age". An idea of his contemporary renown may be gathered from the fact that when George III. and Dr. Samuel Johnson met in the Queen's library, His Majesty closely questioned the famous lexicographer on what he thought of Dr. Hill. Johnson answered that "he was an ingenious man, but had no veracity". Hill asserted that he had seen objects magnified to a much greater degree by using three or four microscopes at a time than by using one. "Now," added Dr. Johnson, "anyone acquainted with microscopes knows that the more of them he looks through the less of the object appears." "Why," replied the king, "this is not only telling an untruth, but telling it clumsily."

The next two chapters describe the learned societies of London. As a tribute to its eclecticism, a whole chapter is given to the Royal Society. Then follow brief but interesting accounts of the Royal Society of Arts, the Royal Institution, and of nearly sixty other societies severally connected with all the ramifications into which systematised knowledge leads men of science, covering in their entirety close on one hundred pages. The undergraduate might read these chapters with profit, before deciding on a future career, and a thesis might be evolved from them, correlating our economic and contemplative life with the growth of these numerous scientific societies. By the way, no mention is made in the book of the London Institution, at one time the rival of the Royal Institution.

The chapter devoted to government and scientific research describes the various departments that watch continually over the private and public needs of our nation, safeguarding and promoting our welfare in times of peace and defending us in the hour of war. No longer is it left to a Bishop Watson to improve the manufacture of gunpowder, or to undertake private afforestation to demonstrate the latent resources of a vacant countryside. Before Parliament would pay a Mrs. Stephens £5000 for divulging her remedy for stone, a Government analyst would detect the soap and snail shells contained in the nostrum. The problem of the resistance of water to moving vessels is nowadays investigated in the experimental tanks of the National Physical Laboratory and not, as it once was, in the vats of Capt. Beaufoy's brewery.

London's heritage of science is abundantly witnessed in her magnificent museums. They show no signs of diminution either numerically or in popularity. They are not curiosity shops on a large scale, but storehouses of information for the studious and pleasure haunts for the general public. Dr. Bather's record contains descriptions of more than three score of them, as well as an interesting foreword on many which have been absorbed or dispersed. Little did men like Tradescant, Lever, and Bullock dream that museums run for profit would be replaced by free institutions worthy of taking a place among the stateliest buildings of the city.

The volume closes with a brief account of the history of the London makers of scientific instruments, by Mr. R. S. Whipple. Besides being skilled craftsmen with a European reputation for the excellence of their work, many of these men have signed the charter book of the Royal Society. Graham's mercury pendulum still beats out the seconds, Ramsden's eyepiece and his dividing engine are well known to all physicists, and the name of Dollond is a household word. Room might have been found for a few more. The most serious omission, however, is the name of Edward Nairne, who lived in Cornhill. His business premises were the rendezvous of men like Canton, Henly, Ingenhousz, and even the shy, retiring Henry Cavendish. Nairne made an electrical machine for Priestley and was among the first to freeze water with the help of an air pump, the receiver of which contained strong sulphuric acid. He was a fellow of the Royal Society and instrument maker to the Royal Exchange.

Throughout the book, the part that London has played in the advancement of science is generously and entertainingly told. Of course, no single volume could fully encompass the scientific history of the City of London. Indeed, the task of the authors must at times have been one of exclusion rather than of inclusion. Much could be said of London's coffee-houses and inns. At "Rawthmell's" the Royal Society of Arts was founded. Wollaston and Thomas Thomson converted Davy to the atomic theory at the "Crown and Anchor". Think, too, of the experiments that have been carried out in the public parks: Faraday, Woodward, Smeaton, Stanhope, and Tyndall in Hyde Park; Benjamin Franklin on Clapham Common; Hawksbee at White Conduit Fields, and so on. What of the Halls of Delight, the Adelaide Galleries, and the Pantheon, that amused our grandparents with the latest inventions and scientific discoveries?

These and other miscellaneous features that come to mind might form another chapter, but doubtless the task which the Council set out to achieve has been satisfactorily accomplished, and the extensive literature on our wonderful city is the richer for this comprehensive volume. A few errors of orthography have been noted. In "The British Association for the Advancement of Science", page 13, Brewster's address should be Allerly and not Allerby. In "London and the Advancement of Science", page 110, Allan should be Allen; page 168, Dionysius is misspelt Dionysus; and page 259, Carlile should be Carlisle. These mistakes are, of course, repeated in the Index, where other errata occur; thus Sisson's Christian name is given as Johnathan; J. S. Smith should be J. E. Smith; J. Clark Maxwell is obviously incorrect, so is Humphrey Davy, and Leeuwerhoek should be Leeuwenhoek.

Insects and Climate.

The Transactions of the Entomological Society of London. Vol. 79, Part 1, April 24. Pp. 247. (London: Entomological Society of London, 1931.) 21*s.*

SOME two years since, Mr. B. P. Uvarov, well known as a leading authority on insect nutrition and metabolism, and more particularly for his work on the periodicity of locust invasions, undertook at the instance of the Dietetics Committee of the Committee of Civil Research, and under the auspices of the Empire Marketing Board, a survey of insects in relation to climate. This work was carried out by Mr. Uvarov with extraordinary diligence, and the result of his labours is embodied in an important contribution which forms a separate part of the *Transactions of the Entomological Society of London* for the year 1931.

The treatise is divided into two principal parts; in the first of which the physical factors of insect life, namely, heat, humidity, light, atmospheric pressure, and electricity, are considered with special reference to the part they play in insect physiology; while the second part is concerned with the practical bearing of the foregoing data on such insect activities as movements, feeding, reproduction, abundance, and distribution; the whole with an eye to problems of economic entomology in the widest sense. It will be seen that the scope of the work is extensive, and the labour of consulting and summarising the literature of the subject must have been great. The author states that out of 1300 books and papers examined, more than 1150, written in eleven languages, furnished material for his summary.

Throughout the work, Mr. Uvarov is careful to point out the necessity of obtaining, where possible, quantitative data both by experiment and observation; thus he shows that in spite of a well-grounded opinion that the swarming of certain insects is influenced by conditions of atmospheric pressure, no definite conclusion on the matter can be reached in the comparative absence of exact statistical data. The same applies to the alleged influence of the electric state of the atmosphere.

An interesting section is devoted to the consideration of seasonal cycles. Pictet's experiments, showing that in six generations a substantial change in the life-cycle of *Lasiocampa quercus* could be produced in adjustment to new conditions, suggest to the author the direct inheritance of acquired response to climatic influence. It may be remembered that a similar suggestion was made many years ago by Weismann in the case of *Heodes phlœas* and its modification *eleus.* But, as Mr. Uvarov reasonably allows, the subject awaits further experimental investigation. The experiments of Süffert with the well-known butterfly *Araschnia prorsa-levana* are spoken of in the same section as giving an entirely new aspect to the problem of seasonal dimorphism, but it may be questioned whether they have added anything material to what had already been established by Merrifield. The latter investigator, it is true, made no use of the term 'diapause' proposed by Henneguy and adopted by Süffert in the sense of a period of dormancy, but the fact itself, with its implications, appears and is recognised in the work of the older authority.

Attention is also directed to the careful experiments of Sir G. A. Marshall with tropical African butterflies. In these, definite results were obtained by the employment of varying conditions of temperature and humidity separately and in combination. The influence of each of these as a factor was clearly established, but it is not easy to see how the results harmonise, as is alleged by the author, with Süffert's "idea that the production of seasonal forms is connected with the type of development, *i.e.* with the presence or absence of a diapause". This dictum seems to call for expansion.

In the concluding section of the work, the data so assiduously collected are applied, under the comprehensive head of climatic influences, to the practical study of the problems of economic entomology. Various means of control of insect-caused injuries of plants and of insect-borne diseases of man are brought under review, and the importance of exact knowledge of climatal conditions for the destruction or checking of insect pests is duly emphasised. The whole leads up to a discussion of the possibility of forecasting the course of events in the life of insects, especially as to "the seasonal appearance of pests, the years of outbreaks, and the ability of an introduced pest to survive in a new country". This calls for an intimate knowledge of many subjects as to which, as the author says, our information is limited and fragmentary.

Nothing is more noteworthy in this admirable treatise than the discrimination with which, while the existence in some cases of relevant and well-attested data is approved, their absence or insufficiency in others is admitted. We are frequently reminded, by the author's method, of Bacon's unsparing analysis of existing knowledge in his "Advancement of Learning". But it is further to be remarked that although, in the course of investigation of causes, stress is constantly laid on the importance of quantitative estimates, the author is on his guard against "a blind faith in statistical methods", which if used without due caution involve mainly a mechanical process instead of a course of reasoning prompted by the valuation on biological lines of the appropriate and relevant data.

F. A. D.

Short Reviews.

International Research Council: International Astronomical Union (Union Astronomique Internationale). Report of Commission 3: *Atlas céleste.* Par E. Delporte. Pp. 6 + 26 cartes. (Cambridge: At the University Press, 1930.) 5*s.* net.

THE confusion caused by the rather indefinite and entirely irrational delimitation of boundaries between constellations has now been successfully attacked by the International Astronomical Union's commission on notation. No reform could be reasonably expected to ignore entirely the old traditional boundaries, or to transfer important stars into adjacent constellations, and this point has been fully recognised by the commission. The suggested scheme defines boundaries everywhere as portions either of hour circles or parallels of declination, but in such a way as to follow approximately the old boundaries. Nearly all stars with Bayer or Flamsteed designations, and all variables discovered before July 1929, remain in the constellation to which they were previously assigned.

A twofold importance attaches to this work, in that the maximum amount of rationalisation is introduced and also that the boundaries are finally standardised, since the approval of the scheme by the General Assembly of the Union makes it internationally authoritative. Delporte's excellent atlas covers the whole sky in 26 maps, showing stars down to the sixth magnitude with the new constellation boundaries. The printing is good, and the scale resembles that of Norton's atlas, although more stars are depicted than in Norton's or other similar atlases. Opposite each map is a table of all stars down to magnitude 4·5, as well as variables, double stars, and important nebulæ or clusters; giving positions for 1875 and 1925, magnitudes, and spectral types. At the end are given two charts in which are inserted the exact right ascensions or declinations of the boundaries at all points. The atlas deserves to rank high amongst others of its size, quite apart from its indispensability for purposes of reference.

Health and Education in the Nursery. By Victoria E. M. Bennett and Susan Isaacs. Pp. xiv + 308. (London: George Routledge and Sons, Ltd., 1931.) 6*s.* net.

THE scientific study of motherhood and of babyhood has made great headway in recent years, and has made possible the production of such a book as this, a book which combines simplicity of statement with accuracy of fact. Its contents were formerly published as two separate volumes, which are here expanded and united. The old-fashioned 'mother's manual' was usually written by a doctor—of course, a man—who restricted his advice to that which concerned the welfare of the body. It is a sign of the times that this book is written by two women, and that it deals at equal length with the bodily and the mental aspects of healthy growth and development.

In a sense, Miss Bennett's task was the easier, because the facts and principles of physiology and hygiene belong to the realm of positive science. Mrs. Isaacs, on the other hand, sometimes has to handle matters of opinion, as, for example, the time and manner of sex instruction for children, if it is given at all. But readers of Mrs. Isaacs' previous publications on similar subjects will be prepared to find that she is always suggestive and never dogmatic.

The Concentric Method in the Diagnosis of Psychoneurotics. By Prof. M. Laignel-Lavastine. (International Library of Psychology, Philosophy and Scientific Method.) Pp. x + 217. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., 1931.) 10*s.* 6*d.* net.

IN the book before us, Laignel-Lavastine presents his methods of examination and treatment of the psycho-neurotic in a series of lectures which were originally delivered at La Pitié Hospital, Paris. His method consists of emphasising the manifold aspects of any case of mental disorder. It is not a case of whether this is a psychogenic or a physiogenic disorder, but how much of this disorder is psychogenic and how much is physiogenic. He describes four concentric zones with a "morbific kernel" at the centre. The zones from within, outwards, are the visceral, the endocrine, the nervous, and the psychic. In every case it is essential to investigate these zones and evaluate their respective values in etiology. His attitude towards psychotherapy is essentially that of the French school headed by Janet. For the teaching of Freud he has no great affection. To those who have confession as part of their religious creed there is no great need for Freud—so says Lavastine.

Maxwell and Modern Theoretical Physics.*

By Prof. NIELS BOHR, For.Mem.R.S.

I FEEL greatly honoured in being given this opportunity of paying a tribute of reverence to the memory of James Clerk Maxwell, the creator of the electromagnetic theory, which is of such fundamental importance to the work of every physicist. In this celebration we have heard the Master of Trinity and Sir Joseph Larmor speak, with the greatest authority and charm, of Maxwell's wonderful discoveries and personality, and of the unbroken tradition upheld here in Cambridge connecting his life and his work with our time. Although I have had the great privilege, in the years of my early studies, of coming under the spell of Cambridge and the inspiration of the great English physicists, I fear that it may not be possible for me to add anything of sufficient interest in this respect, but it gives me very great pleasure indeed to be invited to say a few words about the relation between Maxwell's work and the subsequent development of atomic physics.

I shall not speak of Maxwell's fundamental contributions to the development of statistical mechanics and of the kinetic theory of gases, which Prof. Planck has already discussed, especially as regards Maxwell's fruitful co-operation with Boltzmann. It is only my intention to make a few remarks about the application of the electromagnetic theory to the problem of atomic constitution, where Maxwell's theory, besides being extremely fruitful in the interpretation of the phenomena, has yielded the utmost any theory can do, namely, to be instrumental in suggesting and guiding new developments beyond its original scope.

I must, of course, be very brief in commenting upon the application of Maxwell's ideas to atomic theory, which in itself constitutes a whole chapter of physics. I shall just recall how successfully the idea of the atomic nature of electricity was incorporated into Maxwell's theory by Lorentz and Larmor, and especially how it furnished an explanation of the dispersion phenomena, including the remarkable features of the Zeeman effect. I would also like to allude to the important contribution to the electron theory of magnetism made by Prof. Langevin, whom we much regret not to be able to hear to-day. But above all, I think in this connexion of the inspiration given by Maxwell's ideas to Sir Joseph Thomson in his pioneer work on the electronic constitution of matter, from his early introduction of the fundamental idea of the electromagnetic mass of the electron, to his famous method, valid to this day, of counting the electrons in the atom by means of the scattering of Röntgen rays.

The developments of the atomic theory brought us soon, as everybody knows, beyond the limit of direct and consistent application of Maxwell's theory. I wish to emphasise, however, that it was just the possibility of analysing the radiation phenomena provided by the electromagnetic theory of light which led to the recognition of an essentially new feature of the laws of Nature. Planck's fundamental discovery of the quantum of action has necessitated, indeed, a radical revision of all our concepts in natural philosophy. Still, in this situation, Maxwell's theory continued to provide indispensable guidance. Thus the relation between energy and momentum of radiation, which follows from the electromagnetic theory, has found application even in the explanation of the Compton effect, for which Einstein's idea of the photon has been so appropriate a means of accounting for the marked departure from the classical ideas. The use of Maxwell's theory as a guide did not fail either in the later stage of atomic theory. Although Lord Rutherford's fundamental discovery of the atomic nucleus, which brought our picture of the atom to such wonderful completion, showed most strikingly the limitation of ordinary mechanics and electrodynamics, the only way to progress in this field has been to maintain as close contact as possible with the classical ideas of Newton and Maxwell.

At first sight it might perhaps look as if some essential modification of Maxwell's theory was needed here, and it has even been suggested that new terms should be added to his famous equations for electromagnetic fields in free space. But Maxwell's theory has proved far too consistent, far too beautiful, to admit of a modification of this kind. There could only be a question, indeed, of a generalisation of the whole theory, or rather of a translation of it into a new physical language, suited to take into account the essential indivisibility of the elementary processes in such a way that every feature of Maxwell's theory finds a corresponding feature in the new formalism. In the last few years, this aim has actually been attained to a large extent by the wonderful development of the new quantum mechanics or quantum electrodynamics, connected with the names of de Broglie, Heisenberg, Schrödinger, and Dirac.

When one hears physicists talk nowadays about 'electron waves' and 'photons', it might perhaps appear that we have completely left the ground on which Newton and Maxwell built; but we all agree, I think, that such concepts, however fruitful, can never be more than a convenient means of stating characteristic consequences of the quantum theory which cannot be visualised in the ordinary sense. It must not be forgotten that only the classical ideas of material particles and electromagnetic waves have a field of unambiguous application, whereas the concepts of photons and electron waves have not. Their applicability is essentially limited to cases in which, on account of the existence of the quantum of action, it is not possible to consider the phenomena observed as independent of the apparatus utilised for their observation. I would like to mention, as an example, the most conspicuous application of Maxwell's ideas, namely, the electromagnetic waves in wireless transmission. It is a purely formal matter to say that these waves consist of photons, since the conditions under which we control the emission and the reception of the radio waves preclude the possibility of determining the number of photons they should contain. In such a case we may say that all trace of the photon idea, which is essentially one of enumeration of elementary processes, has completely disappeared.

---

* Address delivered on the occasion of the Maxwell Centenary Celebrations at Cambridge on Oct 1.

For the sake of illustration, let us imagine for a moment that the recent experimental discoveries of electron diffraction and photonic effects, which fall in so well with the quantum mechanical symbolism, were made before the work of Faraday and Maxwell. Of course, such a situation is unthinkable, since the interpretation of the experiments in question is essentially based on the concepts created by this work. But let us, nevertheless, take such a fanciful view and ask ourselves what the state of science would then be. I think it is not too much to say that we should be farther away from a consistent view of the properties of matter and light than Newton and Huygens were. We must, in fact, realise that the unambiguous interpretation of any measurement must be essentially framed in terms of the classical physical theories, and we may say that in this sense the language of Newton and Maxwell will remain the language of physicists for all time.

I do not think that this is a proper occasion to enter into further details regarding these problems, and to bring new views under discussion. In conclusion, however, I am glad to give expression to the great expectation with which the whole scientific world follows the exploration of an entirely new field of experimental physics, namely, the internal constitution of the nucleus, which is now carried on in Maxwell's laboratory, under the great leadership of the present Cavendish professor. In the fact that nobody here in Cambridge is likely to forget Newton's and Maxwell's work, we see perhaps the very best auguries for the continued success of these endeavours. Even if we must be prepared for a still further renunciation of ordinary visualisation, the basic concepts of physics which we owe to the great masters will certainly prove indispensable in this new field as well.

The Temples of Yucatan: Work of the Scientific Restorer.

ALL the great eastward-jutting promontory of Yucatan and Quintana Roo is covered with the ruins of stone temples, erected by architects of great skill, and often beautifully decorated with carvings and wall paintings. Lying between the Usumacinta River and the Caribbean, the region is a low tableland of limestone, scarcely raised from the sea, its general flatness relieved only by a few hills two or three hundred feet high; no rivers run in all the promontory, the abundant rain falling between May and December soaking through the thin layer of soil—frequently no more than a few inches deep—to the natural limestone hollows that serve Yucatan as wells. Sub-tropical, genial, extremely productive where any soil exists, the country's wild covering is light woodland, with peculiar and beautiful vegetation, sheltering hosts of birds and beasts.

This is the background of one of the great puzzles of the history of mankind. For while the evidence is rich, and almost endless, of the high accomplishments of a brilliantly artistic people, the early origins of these people, the reason of their coming to Yucatan, and the causes for the abandonment of site after site, are still mysterious. The most plausible suggestions are no more than guesses, and none is even reasonably adequate to explain the undoubted fact that the builders of many a splendid complex of pyramids and temples appeared in the region, set to work to cut—with stone tools, for these superb architects and masons did not know the use of metal—huge masses of stone; to transport these masses, by man-labour, since they never had the help of the wheel; to set up and carve and paint great buildings; to house and worship their gods, and to practise their astronomical skill; and that after sometimes no more than a hundred years or so, priests and builders marched away, leaving the stately buildings to become the haunt of wild creatures, to be overgrown with trees and forgotten.

According to the calculations of modern archæologists, the erection by the Maya of stone temples (probably preceded by structures of less enduring materials, such as wood and thatch) began before the Christian era; and certain temples in Yucatan were still in occupation, as great religious and civic centres, in the early part of the sixteenth century, when the first Spaniards arrived. From the time of the Spanish conquest, the Maya and their culture suffered eclipse. A sponge was passed over the long record of their scientific and artistic attainments. With a few exceptions, to which students of American archæology owe a debt, the Spanish conquerors felt no curiosity concerning the ideas and civilisation of the vanquished people of Yucatan. They were heathen, their gods were idols; and the great pyramids merely served, when their uplifted temples were despoiled, as quarries for building material and sites for Christian churches.

The clan of learned men, priest-kings, adepts in astronomy, disappeared. They were not only the political leaders, but also the repositories of historical knowledge, experts in the art of recording. The Maya, alone among native American races, possessed a writing method, developed into an accurate system, concerned with historical and calendrical records. These records were carved in stone, and sometimes in wood, engraved in pottery, and painted upon parchment and upon paper made from the leaf of the maguey plant. The latter, collected sedulously by the Spanish missionaries, were burnt in heaps in the market-place of Merida; so careful was the search for these pagan documents that to-day only three Maya manuscripts are known to survive. The art of writing, and of reading the manuscripts and glyphs carved in stone, was irretrievably lost—although, by the irony of fate, archæologists of to-day have puzzled out the meaning of about one-third of the writing by the aid of notes made by a Bishop of Yucatan, and by that aid alone.

Broadly, it may be said that for three hundred years, between the time of the Spanish conquest and the overthrow of the authority of Ferdinand VII., Maya culture was not only crushed in its development, but also ignored. The great series of temples, extending from Copan in the present Republic of Honduras, through Guatemala, through British Honduras, and spreading all over the Yucatec promontory, remained lost in the silence of the sub-tropical woodland; trees grew in the temples and disintegrated the great stone stairways. Maya speech survived; the humble folk, conforming to Spanish ways near towns, nevertheless retained customs and a large proportion of racial purity, especially in outlying regions; and, underneath and side by side with the Christianity patiently taught by missionary priests of Spain, maintained the cult of the ancient Maya gods.

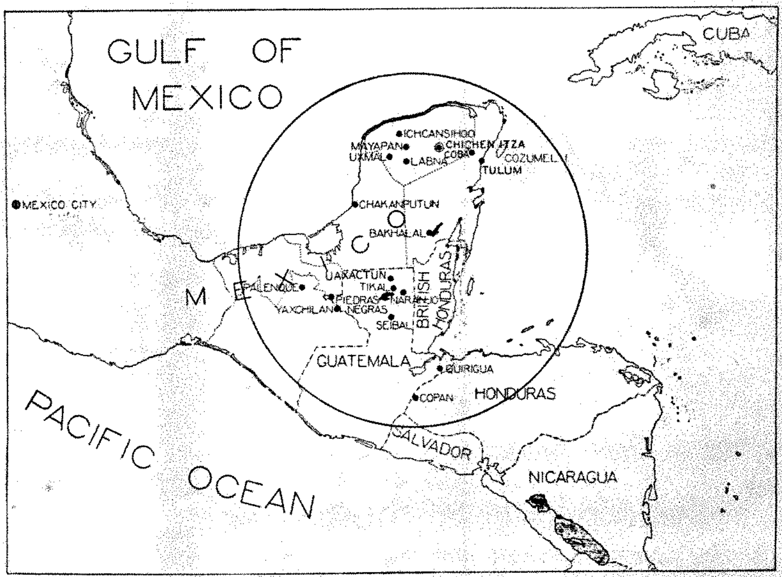

Fig. 1.—Maya region of Middle America.
From "The Temple of the Warriors at Chichen Itzá, Yucatan".

Independence in Spanish America meant the collapse of a fence guarded for three centuries, and travellers came from all parts of the world, and particularly from Europe, to visit the regions formerly forbidden. By the middle of the nineteenth century a few inquisitive and enthusiastic travellers had seen some of the Maya ruins of Central America and Yucatan, and their books had startled a world which up to then regarded Greece and Rome as the chief fountains of romantic antiquity. Most things archæological were measured by these or the Egyptian standard. Even to-day, when ethnology has become a recognised science, it is not always possible to induce the neophyte to consider early American culture as something indigenous, basic, springing from the soil of the New World. If he cannot read Asia into American art, he must have Atlantis as a link.

Nevertheless, John Lloyd Stephens' "Incidents of Travel in Central America and Yucatan" became in the eighteen-forties a 'best-seller'; the drawings of Catherwood, illustrating the genial pen of the author, render this a perennially delightful travel book. The names of the splendid ruins of Copán and Quiriguá, Palenque and Uxmal, became familiar to the English-speaking world. Nothing, however, was done at the time to restore the ruins, or to make scientific examinations; and the work of Maudslay, thirty years later, stands out as the first sustained effort to survey and record certain great sites.

The science of archæology, in fact, was only gradually attaining its stature. The serious worker in the field during the early years was hampered by heavy expenses as well as physical difficulties. The example of Lord Elgin in Greece and of Lord Carnarvon in Egypt was not for some time followed in the Americas by any investigator after Maudslay; but when public interest became extended to—for example—Crete, and Ur of the Chaldees, the time was ripe for enterprise, already engaged in the Old World, to be directed to the untilled fields of the New.

A great step forward was made when the Carnegie Institution of Washington obtained in 1923, from the Government of Mexico, a concession to work for ten years in the magnificent complex of ruins at Chichen Itzá in Yucatan (see Fig. 1).

Work was commenced in 1925, after careful preparations for many branches of scientific study to be followed, as well as for the physical work of clearing and restoration of certain ruins. For the Carnegie Institution, well supplied with funds, studies biology and linguistics side by side with archæological work; scientific surveys and photography are the work of special departments, and the labour of restoring Maya architecture is performed only after careful study. Every tool, thus, is put into the hands of the staff; the Institution has organised one of the best-equipped enterprises that has ever had the good fortune to work in the fascinating field of archæology, east or west.

Not least of the Carnegie Institution's merits is the broad line upon which the department dealing with publications is operated. In all branches of the widely distributed activities of the body, care is taken to make, preserve, and issue records of progress, generously presented to other workers in similar fields, throughout the world. To this department of publications is due a recently issued book invaluable to Americanists, produced in two volumes, dealing with the field work of the Carnegie Institution at the great complex at Chichen Itzá known as the 'Temple of the Warriors'.* The pages measure some 12 in. by 9 in., the first volume containing 485 pages of text and illustrations, while the second consists of plates, of which many are printed in colour. Three persons are responsible for this magnificent record, Earl H. Morris, M. Jean Charlot, and Ann Axtell Morris, and the colleagues are to be congratulated upon work shedding light upon an extraordinary period in the history of Yucatan. When the staff of the Chichen Itzá project began work in January 1925, the slopes of the Temple of the Warriors were densely clothed with bushes, a few axe-cut stumps showing that partial clearing had once been performed. "Presumably, this work was done by Maudslay in 1888. In thirty-seven years the forest would have had ample time to reach this stage of maturity," says Mr. Morris. Dilapidated stone carvings lay on the summit, the stairways were broken, and masses of debris were tangled with vegetation. The original design of the great complex of buildings could scarcely be perceived. To-day, as those fortunate enough to have seen Chichen Itzá lately can say, the whole series of majestic buildings, with fantastic and vivid sculptures in the round, striking reliefs, and mural decorations, stand clear from the surrounding bush. The plan of the series is complicated. From the top of the great main stairway one looks down upon acres of colonnades, while all about the white tops of other pyramids and temples rise from shrubby background under a brilliant blue sky, some still in ruin and others undergoing restoration or completed; the fine pyramid of the Castillo, for example, owes its present dignity to the work of Mexican archæologists commissioned by the Federal Government of Mexico.

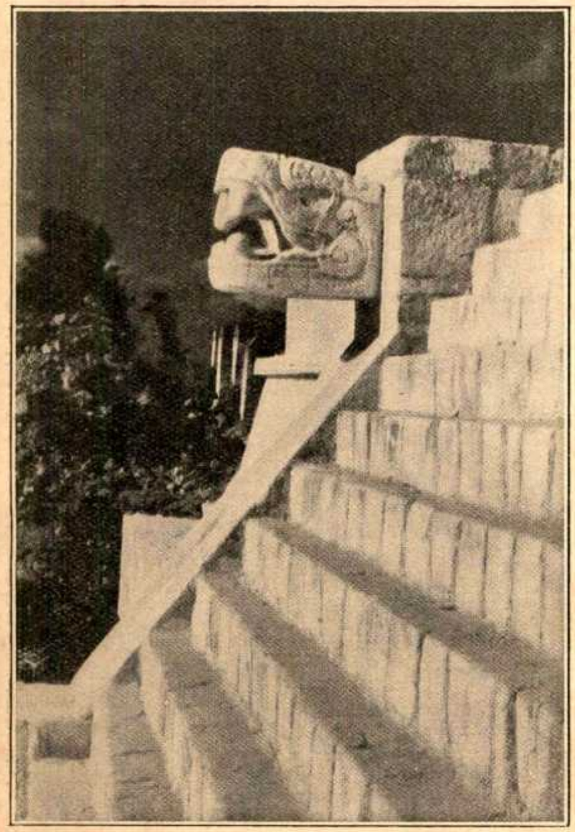

FIG. 2.—Serpent head at the top of north ramp of Warrior's Stairway. Columns of sanctuary of Temple of the Tables in the distance. From "The Temple of the Warriors at Chichen Itzá, Yucatan".

Research, skill, and unlimited patience have made the restoration of the Temple of the Warriors an act of grace. One fears the hand of the restorer, but Chichen has been fortunate; there has been no over-restoration; scrupulous care has been taken to follow ancient lines; and the result is not only satisfying to the eye but also convincing.

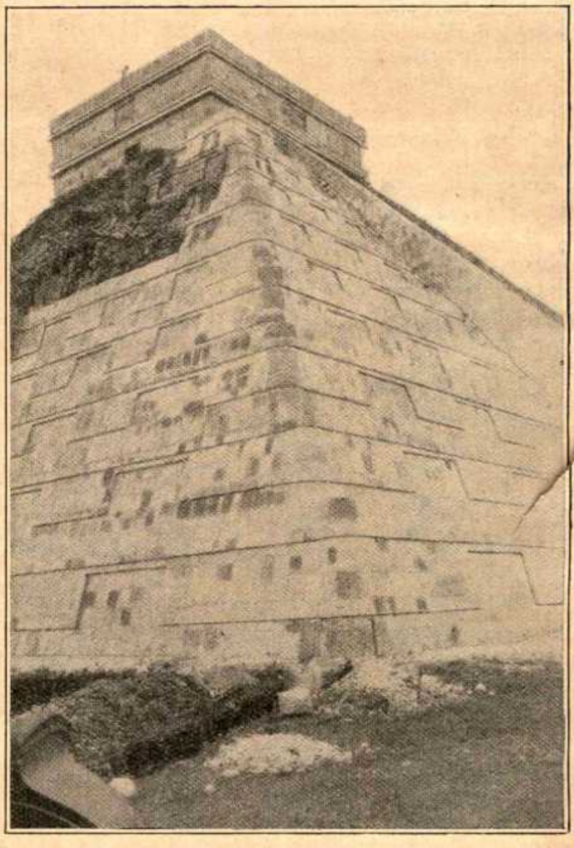

FIG. 3.—North-west corner of Castillo as repaired by Mexican Government. Panelled effect of zones of pyramid is same as finish of substructure of Temple of the Chac Mool. From "The Temple of the Warriors at Chichen Itzá, Yucatan".

The huge serpent columns, the Chac Mool figure, the atlantean altar, the mask panels of the façade, the sculptured bands that run along certain exterior walls, are beautiful examples of Maya art;

* Carnegie Institution of Washington. Publication No. 406: The Temple of the Warriors at Chichen Itzá, Yucatan. By Earl H. Morris, Jean Charlot, Ann Axtell Morris. Vol. 1. Pp. xix+485. Vol. 2. Pp. viii+170 plates. (Washington, D.C.: Carnegie Institution, 1931.) 20 dollars.

but no less interesting are the evidences of the Maya architect's methods of construction. Stairways and vaulted chambers, columns and platforms, and enormous substructures are eloquent of the skill of these vanished people.

The Chichen Itzá project of the Carnegie Institution had devoted four field seasons of some four and a half months each to work on the Warriors when the present volume was written. Work has been under the direction of Dr. Sylvanus G. Morley throughout, who not only planned but also directed operations at Chichen. During the last twenty years, he has devoted himself to the Maya problem, and valuable results have been exemplified in his publications, as well as in the standing monument of the field work in Yucatan.

Few regions equal this strange promontory of the New World in opportunity for archæological investigation. The surface has only been scratched. Individuals and institutions able to share in the unravelling of problems in Yucatan, a chapter of the history of mankind, are to be envied.

Obituary.

Prof. Percy Groom, M.B.E., F.R.S.

Through the death of Prof. Percy Groom, which occurred at Gerrard's Cross on Sept. 16, there has passed away a man with an outlook and interests somewhat exceptional in the senior ranks of British botanists. He was born on Sept. 12, 1865, and entered Mason College, Birmingham, as a student, from which he passed to Cambridge on being elected to an exhibition at Trinity College. He obtained a first class in Part I. and a second in Part II. of the Tripos in 1887, taking botany as his principal subject. Afterwards he was elected to a Frank Smart studentship in botany at Caius College.

During his student life Groom studied for a time at the University of Bonn, where he enjoyed the friendship of the botanists, headed by the eminent Prof. Strasburger, who were making that university the Mecca of so many of the English-speaking followers of the science. He owed much to A. F. W. Schimper, and a delightful appreciation of that gifted man appears as a foreword to the translation of Schimper's "Plant Geography", revised by Bayley Balfour and himself, which was published by the Clarendon Press in 1903. In 1889 he was appointed to the professorship of botany and arboriculture at the Imperial College of Whampoa, in China, and it was doubtless largely owing to this that he was led to turn his attention to the study of trees, and thence to their diseases and economic products, on which he largely concentrated his attention in after years.

On returning to England in 1892, Groom settled for some years in Oxford, migrating to Edinburgh in 1898 to take charge of the classes in plant-physiology under Prof. Bayley Balfour. His stay there was short, as he was appointed in the following year to the headship of the biological department in the Royal Indian Engineering College at Coopers Hill, in succession to Marshall Ward, and on the closing down of that College he came to London as head of the department of botany at the Northern Polytechnic. In 1908 he joined the staff at the Imperial College of Science and Technology, first as an assistant professor, and was promoted to the chair of the technology of woods and fibres in 1911, an appointment he held to the end of his life.

Groom was the author of several books, and he contributed a number of papers, mainly on the anatomy of flowering plants, to various scientific journals, but as time went on he became more and more identified with the 'applied side' of his subject, publishing many papers in various technical journals on timber and forestry topics, as well as on the various diseases which affect wood under the numerous and diverse conditions under which it is employed. He served as a member of many committees concerned with these various matters, and his assistance was often sought by those engaged in industry, as well as by various government departments. One of his last papers was written for the Public Record Office, entitled "A Preliminary Investigation on the Mildew of Book-covers in Relation to Humidity and Temperature of the Air", and this investigation was still going on when he died. His work was recognised by his election to the fellowship of the Royal Society in 1924.

Groom's lectures at the Imperial College, especially those on timber for engineers and others interested in the technical side of the subject, were valued and were well attended. His place will not easily be filled, and as a colleague he will be held in affectionate remembrance by all who knew him.

J. B. F.

Sir William Simpson, C.M.G.

By the death of Sir William Simpson on Sept. 20, after a few days' illness, a great exponent of tropical hygiene has passed away. William John Ritchie Simpson was born in Aberdeen, in 1855, where, after schooling in Jersey, he became a medical student, qualifying in 1876 and taking the M.D. degree four years later. He determined to choose public health as a career, and soon became the first medical officer of health of his native city and lecturer on hygiene in the University.

These posts were relinquished in 1886, when Simpson was appointed chief health officer in Calcutta, a position he held for twelve years, and thenceforward his life was devoted to the advancement of tropical hygiene and medicine. Returning to England, Simpson was elected, in 1898, professor of hygiene in King's College, London, and in 1899 was associated with the late Sir Patrick Manson and others in the foundation of the London School of Tropical Medicine, of which he became one of the lecturers.

From now onwards Simpson was almost continuously engaged in official inquiries into the health of various parts of the tropical dominions of the British Empire. In 1900–1 he was a member of a commission to inquire into the occurrence of dysentery and enteric fever in South Africa and was chief commissioner dealing with an outbreak of plague in Cape Colony, and in 1902 was asked to report upon the causes and continuance of plague in Hong Kong. In 1906 he studied the sanitary conditions of Singapore, in 1908 those of West Africa, of East Africa, Uganda, and Zanzibar in 1913–14, and of the mines and villages of the Gold Coast in 1924. As the outcome of extensive studies on plague, he delivered the Croonian Lectures on this subject at the Royal College of Physicians, London, in 1907.

Simpson was a prolific writer. In addition to many papers and addresses, he published a treatise on plague, a volume on the principles of hygiene in tropical and subtropical climates—the first authoritative work of its kind—and a smaller popular book on the maintenance of health in the tropics. When in India, he edited the *Indian Medical Gazette*, and afterwards was responsible for the *Journal of Tropical Medicine*. In his later years, Simpson was one of the founders of the Ross Institute for Tropical Diseases, in which he became director of tropical hygiene. Here his last work was done, and he died in its hospital.

The services of Simpson were recognised by the bestowal of numerous distinctions: the C.M.G. in 1909, the Order of St. Sava of Serbia, where he had served during the War, in 1918, and the honour of knighthood in 1923. A genial and kindly man, though a strong one when occasion required, he will be greatly missed by a large circle of fellow-workers. R. T. HEWLETT.

WE regret to announce the following deaths:—

Sir J. Hawtrey Benson, formerly president of the Royal College of Physicians of Ireland, and also medical adviser for Ireland for the Colonial Office, on Oct. 9, aged eighty-eight years.

Dr. Thomas A. Edison, world-renowned for his inventions connected with the phonograph, telegraphic and telephonic communication, and the incandescent electric lamp, on Oct. 18, aged eighty-four years.

Dr. Samuel W. Stratton, president of the Massachusetts Institute of Technology, Boston, Mass., who was Director of the U.S. Bureau of Standards from 1901 until 1923, on Oct. 19, aged seventy years.

News and Views.

IT is reported in the daily Press that Dr. J. Papish, assistant professor of chemical spectroscopy at Cornell University, has identified the element of atomic number 87 in samarskite. It is stated to occur to the extent of one part in two million. This element would appear to be the missing alkali following cæsium. The radioactive properties of the element, if any, should be interesting.

ALTHOUGH the recent agitation against the initiation of girls among the Kikuyu of Kenya has now subsided to a great extent, the causes which lay at its root are still operative. It affords an extremely instructive example of how, in dealing with native peoples, the best intentions may often prove positively harmful if not based on a thorough and sympathetic understanding of the full implication of native custom. For example, one point which was raised in the recent trouble by the missionaries was the excessive 'price' demanded in marriage by parents of native girls, which has led to a decrease in marriage and an increase in prostitution, with a related spread of venereal disease. It is, however, pointed out by Mr. L. S. B. Leakey, who discusses the whole situation in a communication in the *Journal of the Royal Anthropological Institute*, vol. 61, Jan.-June 1931, that to a great extent the missionaries have only themselves to blame, in consequence of the requirement that the parents of the girl should sign a certificate at marriage that the whole of the 'bride-price' has been paid. This departure from native custom of a payment on account at marriage with a subsequent settlement by instalments, instead of protecting the bridegroom from a parent's extortion, as it was intended, has deterred young men from marriage and has forced up the 'bride-price'. Mr. Leakey shows how misunderstanding of the character of the initiation customs and their implications, as well as mistranslation of passages in the Scriptures relating to the Virgin Mary arising out of this misunderstanding, brought about a situation which was politically dangerous and has resulted in the moral and physical deterioration of the native. Unfortunately, in present conditions, difficulties such as these are inevitable, yet they are due to causes which might easily be avoided: when the right course is pointed out by those who have the requisite knowledge, it is usually too late. Once there has been a break in tribal custom it is often impossible, as in the present case, to revert to the old law.

ON Oct. 29 occurs the centenary of the birth of the distinguished American geologist and palæontologist, Othniel Charles Marsh. Born at Lockport, New York, Marsh graduated from Yale College in 1860, and after studying geology and mineralogy at the Sheffield Scientific School, studied palæontology and anatomy in Berlin, Heidelberg, and Breslau, and travelled in various parts of Europe. Returning to America in 1866, he became professor of palæontology at Yale College and also Director of the Geological and Palæontological Department of the Natural History Museum founded by the philanthropist Peabody, who was Marsh's uncle. For many years he was connected with the United States Geological Survey; he organised many expeditions to the far west, then a somewhat inaccessible region, and in 1871 discovered the first pterodactyl remains in America, and afterwards brought to light many new genera and families, including the toothed birds and the flying and swimming reptiles. His great reputation was based on his numerous researches on the vertebrates of the western States. Both at home and abroad he received many scientific honours. He died at New Haven on March 18, 1899. His private collection of fossils was bequeathed to the Peabody Museum.

A LETTER from Faraday to William Jordan, of the *Literary Gazette*, now in the possession of Mrs. Charles A. Faraday, of Birmingham, whose late husband was a member of the Faraday family, recalls an incident in his life and explicitly refers to the knighthood which rumour has joined with his name. In the *Literary Gazette* of Aug. 12, 1837, an announcement appeared headed "Sir Michael Faraday" and expressing pleasure at the recent conferment of the honour. Faraday wrote to Jordan on Aug. 15 stating that although he is not sure whether the statement was made in jest or earnest, "it looks so like the latter that I thought I should be unkind in leaving you in error respecting my condition, which is what I trust it will always remain—plain *Mister*". He concludes by asking that no reference whatever should be made to the matter. The original letter was lent by Mrs. Charles Faraday to a member of the Rochdale Literary and Scientific Society and exhibited at a meeting of the Society, and is being reproduced as a facsimile in vol. 17 of the *Transactions* now about to be issued. Inquiries and search have been made, but so far have not succeeded in tracing any former publication of this letter.

AN exhibition to illustrate the development of glass technological research was opened by Sir Richard Gregory in the Science Museum, South Kensington, on Oct. 21. During his opening remarks, Sir Richard gave an interesting résumé of the history of glass-making. Beads of glass were discovered by Sir Flinders Petrie, in an Egyptian grave, which date so far back as 3400 B.C.; while two thousand years later various kinds of coloured glass were made in Egypt. Faraday carried out an extensive series of researches with the object of improving the manufacture of optical glass, and in his Bakerian lecture for 1829 he described glass containing boric oxide, the forerunner of the modern borosilicate glasses. Despite the antiquity of glass-making, however, systematic research is only a matter of the last sixteen years. Immediate attention to the problem of glass was clearly essential as soon as the War broke out, especially with reference to chemical glassware and optical glasses. The recognition of glass technology as a science may be dated to the founding, in 1915, of the Department of Glass Technology in the University of Sheffield. This led to the formation, in 1916, of the Society of Glass Technology, which has now become international in character. As a result of systematic research, our knowledge of the chemistry and physics of glasses has been greatly extended, resulting in a number of new types of glasses and an improvement of old ones. Mechanical development, too, has taken great strides. Such development in research is well, though not exhaustively, illustrated by the exhibition, which is divided into fourteen sections. There is, however, much of importance still to be learnt, especially about the physics and chemistry of glass. It is hoped to keep the exhibition open until the end of the year, and possibly longer.

THE Babirusa of Celebes, of which a pair has been recently acquired by the Zoological Society of London, has been always rare in captivity, and long unrepresented in the Society's collection. The beast is also interesting in itself in more ways than one; in addition to the curious upgrowth of the upper canines of the male through the skin of the face, it is remarkable for its white iris and practically hairless skin, though this nude condition is approached by the African wart-hog. The upgrowing tusks have the appearance of horns, and in fact the Malay name given above means pig-deer, while the horned boars mentioned by Calpurnius as shown in the Roman arena could not have been anything else but this species. Yet Celebes seems to have been outside the knowledge of ancient geographers, which points to the wide range of trade in the Roman imperial period, since the circus could exhibit animals from lands unknown. On the same occasion were exhibited mountain hares in their white coat, zebus, bisons, an elk, a hippopotamus, and seals "with contending bears". If bears were set on to seals in a flooded arena, these would surely have been polar bears, ice-drifted farther south than now, in a period when the reindeer ranged south as far as Germany.

OF late years attention has been directed to some very remarkable variations that have been appearing in the eggs of common fowls. Formerly only varying as a rule from white, through cream—the colour of those laid by the ancestral red jungle-fowl—to brown, they now display a great variety of spotting in dark brown shades on a creamy ground, ranging from fine speckling, like that seen on the eggs of the guinea-fowl, to the freckling of the turkey's egg, and even to heavily spotted and blotched types mimicking the eggs of rails and birds of prey. The fowls that lay such eggs are chiefly the Dutch breeds of Barnevelders and Welsummers, birds which from their appearance have much blood of birds of the Cochin type, such as is found in most of the popular breeds to-day. Even blue eggs, laid by Chilian fowls called Araucanos, have been reported recently, and Mr. C. A. Finsterbusch gives an account of these birds in the *Feathered World* for Aug. 28 (p. 263), illustrated by his own sketches. From these, and from his statements, it is clear that 'Araucanos' are not a fixed breed, but present a great variety of types, any of which apparently may produce eggs of such unusual tints as bluish, purplish, and greenish, the last sometimes spotted with brown, like the European eggs cited above.

THE South London Botanical Institute celebrated its coming of age at the annual meeting and conversazione of members on Oct. 16. Founded and endowed by the late Allan Octavian Hume in 1910, the Institute has done useful work as a centre of botanical interest in south-east London. The excellent library and extensive herbarium of British plants (which includes the herbaria of William Beeby and Frederick Townsend, in addition to Hume's own collection) are available for use by students daily from 2 until 9 P.M. Demonstrations and lectures by well-known botanists are given at fortnightly intervals, and Saturday rambles are conducted by the curator to places of botanical interest around London. A small garden and conservatory are stocked with a selection of British plants. The Institute is governed by a council of fellows, representing London botany, and elected representatives of the members, with Dr. A. B. Rendle as president. Mr. W. R. Sherrin is the residential curator and secretary. Membership is open to any person interested; there is no subscription beyond a contribution of 2*s*. 6*d*. to cover expenses of printing and postage. The address of the Institute is 323 Norwood Road, S.E., about five minutes' walk from Tulse Hill Station on the Southern Railway.

THE ninth Annual Report of the Safety in Mines Research Board, for the year 1930, has just been published (London: H.M. Stationery Office. 2*s*. net), and contains a record of a very large number of researches which are being carried out under the ægis of the Board. There are no less than fourteen different subjects for research, the progress of which is discussed in the report, whilst detailed reports upon them are to be found in the appendices. It is also most gratifying to find that active progress is being made in co-operating with similar boards in other countries, Belgium, France, and the United States being specially mentioned; there is also a reference to co-operation with Germany in the matter of one research, namely, that on wire ropes, and it might well be desired that co-operation with the various German research boards should be extended. All these researches are of international rather than of national importance; they must be conducted by men exceptionally well qualified for the task, and such men are too scarce in all countries for any of their work to be wasted, as it necessarily would be if the overlapping of effort, which has marked the independent work of such boards in different countries, were to be continued. The subjects covered by this report are of the utmost importance to the miner, ranging from explosions through electrical working to explosives, safety lamps, mechanical appliances, and wire ropes, whilst the subject of falls of ground is beginning to receive the attention which its very grave influence on mining accidents unfortunately renders necessary. The report is published at a very low price, and deserves the careful study of all interested in the safety of miners.

AT a meeting of the Newcomen Society held at the Science Museum on Oct. 14, three short papers were read. The first of these dealt with the work of Jolliffe and Banks, contractors, and was by Mr. H. W. Dickinson. Attention had been directed to the work of the firm by the notices of the centenary of the opening of the present London Bridge, which fell on Aug. 1 this year. London Bridge, Southwark Bridge, and Waterloo Bridge, all constructed within the period 1812–1831, were designed by John Rennie and carried out under the superintendence of him and his son, Sir John Rennie; but Jolliffe and Banks were the contractors for all three works. Little has hitherto been generally known of either partner, but Mr. Dickinson was able to show that they were the principal firm of contractors of their time, executing important harbour and drainage works in various parts of the country. These works included the construction of Sheerness dockyard. Edward Banks began life in the north of England and by the time he was thirty years of age had done much canal work, but his partner, William John Jolliffe, was at first a clergyman. Their partnership lasted about thirty years. They both died in 1835, at Tilgate Lodge, Sussex, and they are buried in adjoining parishes in Surrey, Jolliffe in Merstham Church and Banks in Chipstead Churchyard. Banks was knighted in 1822, being the first professional engineer in the country to receive that honour. There is an account of his life in the "Dictionary of National Biography", but it is meagre and unsatisfactory, and Mr. Dickinson was able to give much interesting information which has hitherto been unavailable.

IN many of the schools which train the blind for various handicrafts and professions, the principles of electricity and magnetism are included in the standard curriculum. One of the difficulties in teaching the blind is to enable them to form mental pictures of the various phenomena. In the *Electrical Times* for Oct. 8, there is a description of Braille models invented by Dr. F. W. Alexander, of Teddington, which have proved a great help to teachers. Using simple materials like plywood and nails, he constructs models which show the positions of the lines of force between magnets in various positions, the current flow in the armature of a dynamo, the magnetic reactions in a simple motor, the amplitude variations of an alternating current, and similar theorems graphically by means of touch. This method of teaching the blind has much to recommend it, and the models are readily understood by those who have been born sightless. We understand that the method is novel and has not been in use before. Blind workmen are sometimes employed in making wireless sets, their affliction developing a marvellous sensitivity of touch.

ON account of the present world-wide economic depression, the sixteenth International Geological Congress, to be held in the United States, has been postponed for one year—to June 1933. A revised circular has now been issued, accompanied by an excellent map showing the routes to be followed on the various excursions before, during, and after the meetings at Washington. As a result of responses to the announcements made in the first circular, the following list of topics for discussion is proposed: measurement of geological time; batholiths and related intrusives; zonal relations of metalliferous

(*Continued on p.* 723.)

Supplement to NATURE

No. 3234 OCTOBER 24, 1931

The Evolution of the Universe.

SUPERFICIALLY the most significant feature of the discussion at the British Association on the evolution of the universe, the contributions to which form our Supplement this week, was the question of the relation of the physical universe to life and mind. Criticisms of the physical arguments gathered so closely round the neglect of consciousness in the physical scheme that Sir James Jeans felt it necessary to explain at the end of the meeting that physicists were not necessarily ignorant of the existence or importance of consciousness in the universe, but, as members of Section A of the Association, they were not called upon to take it into account in considering their own problems.

Sir James's remark was timely and, in view of certain aspects of the discussion, was undoubtedly justified. At the same time, there was perhaps more cogency, implicit if not expressed, in the criticisms in question than was met by his reply. It was undoubtedly the physical universe, and the physical universe only, that was under examination, but that is a big thing and eternity is a long time. Before consciousness can be ignored in considering the indefinite future and past, it must be shown that, throughout the whole history and extent of this physical universe, consciousness can have no possible effect on it. Until that is established, such words as 'inevitable' and 'certain' must be left out of the discussion, and unfortunately they were not.

The universe on its first introduction to the unprejudiced inquirer is a collection of objects of various kinds—large, small, heavy, light, plain, coloured, moving, stationary, animate, inanimate, solid, liquid, gaseous, tangible, intangible, visible, invisible, and so on. There is no obvious reason why the distinction between animate and inanimate should differ in kind from that between any of the other diversities, but in the course of scientific investigation it has been found that all the others can be correlated with one another and expressed as functions of a very few fundamental concepts, while the peculiar characteristics of animate objects remain obstinately and completely outside. Two possible attitudes to this situation immediately suggest themselves: we may assume a fundamental duality between a 'physical world' and a 'world of life', or we may attribute the intractability of life merely to our ignorance of the full potentialities of matter.

Now, these attitudes are clearly incompatible, yet they are often unconsciously adopted by the same thinker. When, like Sir James Jeans (to whom his critics, however much they may disagree with him, must concede the great merit of embodying his ideas in definite phrases at which they can fling their darts), we speak of the evolution of the 'physical universe' as a self-contained problem, we adopt the first; and when, like General Smuts, we speak of the 'origin of life from matter', we adopt the second. It would be interesting to know to what extent the two assumptions were tacitly associated at the backs of the minds of the several speakers.

An attitude which, whether right or wrong, is consistent is the assumption of duality as a temporary expedient, coupled with the effort to interpret the comprehensive universe, starting independently from the two sides of matter and mind. This is what is in practice being done—at least in part. The approach from the side of matter constitutes generalised physics, and the approach from the side of mind constitutes psychology.

From the physical direction of approach it is natural to look for the emergence of life at some time in the past and to express it as a possible function of such physical concepts as time, space, mass, or their equivalents—'the origin of life from matter'. This is a laudable endeavour, although while we remain in ignorance of this mysterious function it must stop short of the final generalisation of a 'physical universe'. The psychological direction of approach, on the other hand, offers a diametrically opposite view. Space-time, mass, energy and the like give place to such concepts as will, purpose, desire; and matter becomes not the source of life but at most its tool and perhaps its creature. Mechanical action is no longer the ground out of which volition has sprung ; it is the ultimate point which volition can reach. Just as such mechanical human actions as breathing and blood-circulation are expressed as mental acts become automatic through age-long practice, so, as soon as psychology realises its cosmic significance, the orderly movements of the physical world must tend to be expressed as the functioning, grown habitual, of a universal consciousness which in its youth may have been as wayward as an irresponsible child and in its old age may exhibit the disturbing effects of 'repressions' associated with such waywardness.

We cannot escape from this possibility in its most general form. If we assert duality, we are confuted by the obvious interaction between mind and matter in living creatures. If, on the other hand, we pursue the study of matter in the hope that an interpretation of mind in physical terms will one day be reached, we cannot deny the right of the psychologist to pursue the study of mind in the hope that an interpretation of matter in mental terms will one day be reached. The 'physical universe' is a convenient fiction for the former pursuit, but we have no right to call it anything else. With appropriate reservations it may be likened to the carrot held before the donkey. It makes him run but it has nothing to do with what awaits him at the end of the road. From this point of view there is a world of meaning in Prof. de Sitter's claim, made on quite other grounds, that the physical universe is a hypothesis.

When we leave these rock-bottom considerations and contemplate the discussion in its purely physical aspect, we again see Prof. de Sitter's suggestion as one of the outstanding points. It is, indeed, so obvious as to be in grave danger of being overlooked : the closed universe has never been observed, but is assumed in order to correlate facts that are observed ; it is therefore a hypothesis. In this respect, as Prof. de Sitter says, it resembles the atom, but there appears to be an essential difference. There is no reason, so far as we know, why, if it is real, it should not be observed in the future if the rate of increase of telescopic power exceeds its rate of expansion. In that event it would cease to be a hypothesis and become a phenomenon. But the atom, by the requirements of its own nature, is inherently unobservable and can never be other than a hypothesis. If, therefore, it has properties which are impossible to phenomena, it has a legitimate defence. But if the universe, which may one day be observed, has such properties, then we can definitely say that it is a hypothesis which is wrong. Possibly "the velocity of change of the quantity . . . which . . . is interpreted as the 'radius of the universe' has nothing to do with the rate of evolutionary change of stars and stellar systems ", but in that case we cannot rest content with the contradiction but must change the interpretation of that quantity, in the sure and certain hope that it has an interpretation in terms of familiar conceptions.

Even apart from this essential difference between the universe and the atom, however, the remarkable and in many ways mysterious parallelism between the details of the atomic hypothesis and direct experience must make us hesitate before concluding that the two types of time-scale in question are inherently irreconcilable. The second law of thermodynamics, the Michelson-Morley experiment, and—perhaps most striking of all—Sir Arthur Eddington's bombshell of a correspondence between the characteristics of the electron and those of the universe, afford sufficient examples of alternative interpretations which appear to be completely equivalent to make us doubt a final incompatibility, even if one were theoretically permissible.

The most profound significance of the discussion as a whole, however, lay in the fact that the various speakers not only had no common starting-point but also made no attempt to find one. Possibly this was inevitable under the conditions of the discussion, but if so, so much the worse for the conditions. We need not return to the basis of scientific thought to see this ; it is only too evident on the higher platform of purely physical ideas. It is an instructive, though exceedingly difficult, task to examine the various contributions in order to discover what was implicitly assumed ; and when we do this, however imperfectly, we find a diversity which not only makes us wonder, but also directs attention to the urgent need of defining what actually is the basis of modern physical theory.

Sir James Jeans paid homage to the second law of thermodynamics, which to Sir Oliver Lodge was an idol against which philosophers were to be warned. General Smuts accepted the law but claimed that life was the result of the odd chance which it allows — a remarkable claim, which implies that the chance of life persisting for a single moment longer is inconceivably small. The Bishop of Birmingham started from particular facts (or statements having the appearance of facts) rather than principles, but the arguments which followed seemed to spring more from independent beliefs and hopes than from the promised source. Those beliefs and hopes had no audible echo in the remarks of the other speakers, and the chief ' facts ' were treated with scant respect by Profs. de Sitter and Millikan respectively. Sir Arthur Eddington and the Abbé Lemaître built on the field equations of relativity, and the former also on the wave equation of an electron—grounds which were not openly challenged, but which were by no means universally shared. Prof. Milne, like Prof. Millikan, gave a very suggestive account of a particular process, but that process can scarcely be said to lie at the heart of the question. C'est magnifique, mais ce n'est pas l'univers. Severely local in time and space, Prof. Milne was perhaps justified in assuming the conservation of energy, but Sir James Jeans, taking a wider outlook, had previously spurned that principle. This difference might be reconciled by a slight change in the definition of the word ' energy ', but only the previous day Prof. Bohr had been telling Section A of the Association that the concept of energy seemed to be inapplicable to atomic phenomena, and that in the sun and stars the energy might come from nothing! What about the evolution of the universe in that case ?

The question that sounds insistently through all this confusion is : What is the fundamental basis of physical thought ? " Give me whereon to stand, and I will move the earth," said Archimedes. Where do we stand in order to move the law of conservation of energy ? It does not matter in the least whether Bohr's suggestion is upheld or not. The fact that it was seriously made shows that there is some foothold, beneath the law in question, which physicists were assumed to share, and that foothold is deeper than anything that was assumed at the discussion we are considering. It is idle to suppose that we can move the universe from a higher level than that necessary to move a physical theory, and the ordinary man, for whom the discussion was primarily intended, might well ask why a company of some of the world's leading thinkers, discussing the world's weightiest problem, should not at least start from common fundamental principles. As it stands at present, the chief value of the discussion lies in the incidental contributions to advanced physical thought which it elicited ; but if it leads ultimately—perhaps by way of an *ad hoc* discussion at some future meeting of the British Association—to a definite formulation of the basic principles of physics, it will perform a service far more in accordance with its original purpose. H. D.

Contributions to a British Association Discussion on the Evolution of the Universe.

By Sir James Jeans, F.R.S.

We are, of course, discussing only the physical universe. Here strict determinism reigns, because even if there is no determinism in the behaviour of individual atoms, there are so many atoms in even the tiniest bit of matter that we may take an average. The laws of probability provide something which is, for our present purpose, equivalent to a strict causal determinism.

It follows that the final state of the universe is inherent in the present state, just as this present state was inherent in the universe at its creation. The physical universe never has any choice—it must inevitably move along a single road to a predestined end. What we are calling evolution is like the rolling of a train along a single-track line, with no junctions of any kind.

The various possible lines of development for the universe are like an enormous number of single-track lines ; and as we do not know which track we are on, it is futile to discuss at what particular spot it ends. But the second law of thermodynamics makes it possible to discover in what kind of country it ends, and this is really the information we want.

Strictly speaking, this law does not deal in certainties, but in probabilities—although of a somewhat unusual kind. The number of particles in the universe is probably of the order of 10^{79}, and all the odds to which we are introduced by the second law involve very high powers of 10^{79}. We need not trouble to differentiate too closely between such long odds and certainties.

This law teaches that the universe will ' evolve ' through a succession of states of ever-increasing entropy, until it ends in the final state of maximum entropy. Beyond this it cannot go ; it must come to rest—not in the sense that every atom in it will have come to rest (for maximum entropy does not involve this), but rather in the sense that its general characteristics cannot change any more. Yet if someone asserts that this will not happen, and that the universe will move to a state of *lower* entropy than the present, we cannot prove him wrong. He is entitled to his opinion, either as a speculation or as a pious hope. All we can say is that the odds against his dream coming true involve a very high power of 10^{79}—in his disfavour.

The question of discovering the final state of the universe is merely that of discovering how far its entropy can increase without violating the physical laws which govern the motions of its smallest parts.

General considerations show that the universe still has a long way to go. It can increase its entropy by distributing its radiant energy more uniformly; at present this is still very far from being uniformly distributed. Out in the farthest depths of space the density of radiant energy corresponds to a temperature of less than one degree above absolute zero: in the interstellar spaces of the galactic system, three or four degrees only; near the earth's orbit about 280 degrees; at the sun's surface about 6000 degrees; at the sun's centre perhaps 40 or 50 million degrees. The entropy is increased by equalising these temperatures: that is why energy flows from the sun's hot centre to its cooler surface, and why it then streams out into space, past the earth's orbit into the cold and dark of interstellar and intergalactic space. There can be no end until all these regions are at the same temperature, with radiant energy diffused uniformly through space.

All radiant energy has its origin in atomic disturbances. Each atom is a sort of storehouse of energy or mass—we now believe the two to be identical—and at intervals, either spontaneously or through interference from outside, an atom may discharge some of its energy or mass into space in the form of radiation. This wanders through space like a sort of bullet of radiation travelling with the velocity of light; we call it a photon. Now the so-called 'cosmic radiation' which falls on to the earth from outer space appears, so far as we can tell, to consist of photons whose masses are comparable with those of complete atoms. Indeed, the two most massive types of photons so far detected in this radiation are found, to within errors of measurement, to have precisely the masses of the helium and hydrogen atom respectively. The simplest interpretation is that these photons originate out of the complete transformation of atoms of helium and hydrogen into radiation. But this is not the only interpretation, nor, I think, the most probable. All atoms consist of protons and electrons in equal numbers, so that their masses are (approximately) exact multiples of the mass of the hydrogen atom, which contains one of each. If an electron and a proton were to neutralise one another in any atom whatever, the atomic weight of the atom would be reduced by unity, and the atom would eject a photon of mass equal to the hydrogen atom. In the same way, if an α-particle were to neutralise itself by combining with two electrons in any atom whatever, the resulting photon would have a mass equal to the helium atom.

Although not everyone agrees, this seems to me the most plausible interpretation of the two most penetrating constituents of the cosmic radiation. I think they provide evidence that matter can be annihilated, and point to a general degradation of complex atoms in the direction of simplified structure and decreasing atomic weight.

On this view, electrons and protons must be regarded as concentrated stores of energy, which are capable of being set loose and dissipated in the form of radiation. The entropy of the universe is increased by this process, and the final state of maximum entropy is one in which every electron and proton which is capable of annihilation has been annihilated.

The question at once arises as to how many of the 10^{79} or so electrons and protons which form the universe are subject to annihilation. They may all be, in which case the final state of the universe will be one in which all matter is dissolved into radiation, and nothing remains but radiation traversing empty space. Or again, only special types of atoms may be liable to annihilation, just as only special types are liable to radioactive disintegration. In this case the final state will be one from which these atoms, like the radioactive atoms, will all have disappeared. There will be a universe of cold inert matter and of uniformly distributed radiation of very feeble intensity.

Amongst a mass of theoretical possibilities, the one certain fact is that if the atoms of our earth are undergoing annihilation, their rate of destruction must be exceedingly slow; their average life must be of the order of 10^{18} years at least, or else the earth would be markedly hotter than it is. This suggests the possibility that annihilation may only occur in types of atoms which are not found on earth—possibly atoms of higher atomic weight than terrestrial atoms.

Many considerations suggest that the stars produce their radiation by the annihilation of their substance. Perhaps the strongest, and certainly the most clear-cut, is that the stars which appear to be the youngest (such as binary stars describing close circular orbits) are statistically the most massive. It looks as though the stars lost a large part of their mass in the course of their lives, and this can only mean that a large number of their atoms, or a large part of these atoms, undergo annihilation. If so, our terrestrial atoms may well be a sort of indestructible ash, the relics of more complex atoms after all that can be annihilated has been—just as lead and helium are the relics of radioactive atoms of greater atomic weight.

There is, however, an alternative possibility. If matter is capable of annihilation, the general principles of the quantum theory show that the total amount of this annihilation must consist of two parts. The first is an annihilation which goes on steadily, regardless of external conditions of temperature and pressure, just as radioactive disintegration does. The second is an annihilation which is incited by high temperature, and whose rate increases with an increase of temperature. Calculation shows that this will only come into play when the temperature begins to approach a million million degrees.

Clearly if the cosmic radiation we receive on earth proceeds from annihilation, it must be annihilation of the first kind; for radiation which had been produced by annihilation of the second kind, and so at a very hot place, would all be absorbed by matter before it could climb down the very long temperature gradient and emerge into outer space. But it is possible that it is mainly radiation of this second kind which, after innumerable absorptions and re-emissions, or repeated softenings, appears as the ordinary light of the sun and stars. Thus many astronomers think that matter is annihilated in appreciable amount at high temperatures only, and that the annihilation at low temperatures is negligible. On their view, terrestrial atoms escape annihilation, not because they are specially indestructible, but because they are specially cool.

Yet this view is confronted by many difficulties. The cosmic radiation cannot be produced by this high temperature annihilation, and yet this is of vast amount—comparable at least with the radiation of all the stars. Also, for the heat of the stars' interiors to produce annihilation, their temperatures must approach a million million degrees. This requires what so far seems to be an impossibly high temperature-gradient inside the star. Again, such high temperatures, and such a mode of generation of energy, would, so far as we can see, make the stars unstable and, indeed, explosive structures. The best simple analogy to such a structure is a keg of gunpowder, with its centre raised to the flash-point of the powder. Nevertheless, it must be admitted that we are far from definite knowledge on these questions, which are still in the stage of very heated discussion.

A further possibility is that stellar light and heat do not result from annihilation of matter at all, but from some less fundamental change in atomic structure. If so, we are no longer compelled to postulate unduly high temperatures at the centres of the stars; this difficulty disappears. If the atomic changes are spontaneous, like radioactive change, the difficulty as to stability also disappears as, indeed, it does whatever the origin of the energy. But these milder changes cannot provide enough energy for the long lives—millions of millions of years—through which the stars have, to all appearances, existed. The equipartition of energy in the motion of the stars in space, as well as in the internal motion of binary systems, and also the small masses of what appear to be the oldest stars, all point to extremely long stellar lives. To provide adequate total radiation, throughout these, we need complete annihilation of matter; nothing less drastic will serve. If we cannot have this, we must conclude that the universe of stars is still quite young, in spite of looking so old; its many appearances of great age must all be deceptive.

This seems far more possible than it did even a year or two ago. Indeed it derives much support from recent developments in the theory of relativity. These suggest, somewhat strongly, that the whole universe may be expanding, while recent astronomical observations, if they have been rightly interpreted, indicate that it actually is expanding, and this at so rapid a rate that it becomes a mere transitory and ephemeral structure compared with what we recently thought: the spectra of the great extra-galactic nebulæ seem to indicate that these bodies are running away from one another so fast that they cannot have been running for long. This reduces the whole life of the universe to a matter of hundreds of thousands of millions of years at most—and incidentally, in so doing, brings almost complete chaos into the already chaotic problem of stellar evolution.

Another possibility—nearly but not quite identical with the foregoing—is that the universe retains its size, while we and all material bodies shrink uniformly. The red shift we observe in the spectra of the nebulæ is then due to the fact that the atoms which emitted the light millions of years ago were larger then than the present-day atoms with which we measure the light—the shift is, of course, proportional to distance. The final end here is a universe in which all matter has shrunk to nothing.

On the other hand, if the universe is expanding, the stars are merely pouring out their radiation into a bottomless pit, since the space to be filled with radiation is for ever increasing in amount. The total energy of the universe is for ever decreasing in amount, because radiation does work in pressing out the boundaries of the universe—just as a gas loses energy and so cools, when it expands and presses back the boundaries of its ' universe '. Thus the mass of the stars is continually changing into energy, while this energy in turn changes into mere additions to the size of the universe. There is conservation neither of mass nor of energy. Nor, if the evidence of the cosmic radiation is to be trusted, is there any conservation of matter. Matter turns into energy and energy into mere bigness of space.

Suppose some infallible oracle offered to give a ' Yes ' or ' No ' answer to two scientific questions for each of us. Personally, I think I might choose as my two questions :

1. Does the main energy of stellar radiation come from the annihilation of matter ?
2. Is the universe expanding at about the rate indicated by the spectra of the nebulæ ?

By Abbé G. Lemaître, Observatory, Louvain.

I PROPOSE to give some answer to the two questions raised by Sir James Jeans, which so clearly summarise the present state of the problem of the evolution of the universe. I will begin with the second question, because I think that its solution may throw some light on the first one : " Is the universe expanding at about the rate indicated by the spectra of the nebulæ ", the atomic constants not being modified by some artificial change of gauge ? I add these words, because it is clear that any artificial expansion could be provided by arbitrarily varying the units of length, time, and mass. Expansion of the universe is in some sense relative : it is relative to the whole set of essential properties of matter being assumed to be constant.

The expansion of the universe is a matter of astronomical facts interpreted by the theory of relativity, with the help of assumptions as to the homogeneity of space, without which any theory seems to be impossible. I shall not discuss the legitimacy of this interpretation, as I do not know any definite objection made against it and this is not the place; and it is not necessary to give a new popular version of the leading principles of the theory of relativity. I shall rather try to show that the universe must be expanding, or rather that the most necessary processes of evolution are contradictory to the view that space is and has always been static.

It has been pointed out by Sir Arthur Eddington that a static universe is unstable, and he proposed the problem of finding the possible causes of its expansion. He suggested that such a cause might be the formation of condensations. I obtained recently a solution of this problem, and the main results are as follows :

When the expansion is already started, the effect of kinetic energy or pressure of radiation is quite negligible. On the contrary, pressure is the chief factor in the question of instability of a static universe. If the pressure were rigorously zero, the expansion could never appear. But, if the pressure (or kinetic energy) is not zero, any diminution of pressure must start the expansion. For example, a world full of radiation starts expanding as soon as the radiation can transform itself into matter.

When condensations exist or are formed, the problem is complicated by gravitational effects ; but it can be shown that the general expansion of the universe depends entirely on the density of kinetic energy or of pressure at the places where the gravitational influences of the condensations cancel one another. I call these places (for brevity) ' neutral zones '. Condensation in itself has no direct effect whatever on the stability of the universe : but condensations would necessarily induce a rarefaction at the neutral zone and so a diminution of the density of kinetic energy at the neutral zone ; and this must induce expansion.

We can conclude that any general process of condensation, occurring in a world where the kinetic energy does not vanish, must induce expansion. Therefore, practically, the expectation of Sir Arthur Eddington is fully confirmed. For example, formation of stars out of a primeval gas starts the expansion ; formation of extra-galactic nebulæ out of a uniform mass of gas or of stars starts the expansion. I think that these results add much weight to the fact that the actual velocity of expansion fixes a limit to the time scale of the evolution, as we must rule out of our speculations every process which would start a premature expansion of space.

Even if we had no experimental evidence of the expansion of space, considerations of stability would fix a limit to the time-scale of evolution. The reason is that, if the universe has existed for too long a time, any general process of condensation would be contradictory to the actual value of the density of matter. Although this quantity is not known with great accuracy, its value may give some idea of the maximum scale of evolution. I find that any general process of condensation, even of very moderate intensity, cannot have happened earlier than a few hundred thousand million years ago.

As stated by Sir James Jeans, this brings almost complete chaos into the already chaotic problem of stellar evolution. A complete revision of our cosmological hypothesis is necessary, the primary condition being the test of rapidity. We want a 'fireworks' theory of evolution. The last two thousand million years are slow evolution: they are ashes and smoke of bright but very rapid fireworks.

I think that the key of the problem is afforded by the discovery of the cosmic rays. Cosmic rays are of enormous energy. Their intensity is estimated to be about one-tenth of that of the light coming to us from the stars. If these rays are really cosmic, their energy is much bigger than that of the light of the stars, because it must be of equal intensity all over space. Simple computation shows that the energy of cosmic rays is comparable in amount to the whole energy of matter, being possibly one thousandth, and at least one hundred thousandth, of the total energy of matter.

If the cosmic rays originated chiefly before the actual expansion of space, their original energy was even bigger, and it has been reduced by the expansion in the ratio of the change of the radius of the universe during the time of their transmission through free space. We get photographs of nebulæ at a distance of about one hundred million light years; light from these nebulæ travelled through space during about one hundredth of the time of expansion. It does not seem improbable that the cosmic rays have travelled around one hundred times longer and were really produced by the process of the formation of the stars. This may give the solution of the puzzle. The only energy we know which is comparable to the energy of the cosmic rays is the matter of the stars. Therefore it seems that the cosmic rays must have originated from the stars.

Now the stars are surrounded by an atmosphere, and an atmosphere would altogether prevent any escape of cosmic rays from the inside of a star. The explanation seems to be that the cosmic rays went off from the stars at a time when the stars had no atmosphere. The stars are born without atmosphere; the atmosphere evolved after the escape of the cosmic rays.

We are thus led to the conclusion that the stars were born some ten thousand million years ago without atmospheres, and that the cosmic rays are outstanding features of the formation of a star.

How could we explain such a phenomenon as that? Sir James Jeans has given strong reasons for admitting the existence of atoms of considerably higher atomic weight than our actual dead atoms. Cosmogony is atomic physics on a large scale—large scale of space and time—why not large scale of atomic weight? Radioactive disintegration is a physical fact, cosmic rays are like the rays from radium. Have they not escaped from a big scale super-radioactive disintegration, the disintegration of an atomic star, the disintegration of an atom of weight comparable to the weight of a star.

The birth of a star would be an atom of weight somewhat greater than the actual weight of the star, and the star would be formed by the super-radioactive disintegration of its original atom. It is conceivable that the greater part of the products of disintegration would be kept back together by the gravitational attraction of such a massive atom, although a considerable part, say one thousandth, should be able to escape into free space at the beginning of the evolution, before the products of disintegration are numerous enough to form an atmosphere. Cosmic rays would be glimpses of the primeval fireworks of the formation of a star from an atom, coming to us after their long journey through free space.

The frequency of cosmic rays is, of course, very high; nevertheless, it may be thought to be too low to be the by-product of such a tremendous disintegration of matter. However, it must be realised that the observed frequency of the cosmic rays is not the original frequency. The original frequency has been reduced in the ratio of the expansion of space, and was at least twenty times greater than the observed frequency.

I think that a possible test of the theory is that, if I am right, cosmic rays cannot be formed uniquely of photons, but must contain, like the radioactive rays, fast beta rays and alpha particles, and even new rays of greater masses and charges. I have shown that the momenta of such rays must be reduced by the expansion in about the same ratio as that of the photons.

The mass of a star should be determined by the weight of its original atom, and it is conceivable that stars might be born with different masses. If the mass of the original atom is too big, the star must be finally broken up by radiation pressure, and the original atom must give birth to a cluster of stars, chiefly formed by stars of maximum mass. If the star comes from an atom, both masses and luminosity are determined by the weight of the original atom. Thus this theory accounts for a mass-luminosity relation.

The actual theory does not completely bring order into the chaotic state of cosmogony imposed by the fact of the expansion of space. Explanation of the approximate equipartition of energy between the stars, or evolution with loss of mass along the Russell diagram, might be dismissed with regret. But I do not see any way to retain these processes of evolution, because they are altogether too slow.

If I had to ask a question of the infallible oracle alluded to by Sir James Jeans, I think I should choose this: "Has the universe ever been at rest, or did the expansion start from the beginning ?" But, I think, I would ask the oracle not to give the answer, in order that a subsequent generation would not be deprived of the pleasure of searching for and of finding the solution.

If the total time of evolution did not exceed, say, ten times the age of the earth, it is quite possible to have a variation of the radius of the universe going on, expanding from zero to the actual value. I would picture the evolution as follows: At the origin, all the mass of the universe would exist in the form of a unique atom ; the radius of the universe, although not strictly zero, being relatively very small. The whole universe would be produced by the disintegration of this primeval atom. It can be shown that the radius of space must increase. Some fragments retain their products of disintegration and form clusters of stars or individual stars of any mass. When the stars are formed, the process of formation of the extragalactic nebulæ out of a gaseous material, proposed by Sir James Jeans, could be retained for the star-gas filling the space. The numerical test works out equally well for this case.

Whether this is wild imagination or physical hypothesis cannot be said at present, but we may hope that the question will not wait too long to be solved.

We want two things. First, a theory of nuclear structure sufficient to be applied to atoms of extreme weights. For these atoms, the problem cannot be separated into a nuclear problem and a problem of surrounding electrons ; because it is easily seen that the K ring would merge into the nucleus. We must wait, but we may trust the physicists that we do not have to wait too long. The second thing we want is a better knowledge of the nature of the cosmic rays. The correlation of the theory of nuclear structure with further observations on the cosmic rays must answer yes or no to our question ; and we shall prefer this answer, however incomplete it may be, to any answer of any infallible oracle.

By Prof. W. de Sitter, Observatory, Leyden.

I HAVE been asked to make a short contribution to this discussion about the evolution of the universe. I hope you will find it short, although its length will, I fear, exceed the diameter of the earth's orbit round the sun. This way of expressing a time in a unit of length is perhaps somewhat unusual. To have a distance expressed in a unit of time is, of course, very familiar. A light-year has become an accepted unit of distance.

I have purposely used the inverse method to direct attention to the fact that the corresponding units of time and of space are so very widely different in relation to actual phenomena. The diameter of the earth's orbit enormously exceeds all lengths that we ever come across in our daily life, whilst a quarter of an hour is considered a short interval. Similarly, a thousand million light-years is a long distance, in fact many times greater than any actual distance of which we have certain cognisance, but a thousand million years is a short time in the evolution of the universe. It is only a third or a quarter of the accepted age of the earth, and I do not think geophysicists will be ready to take off even one single zero. We believe, and so far as I can see on good grounds, that the ages of the sun and the majority of the stars are at least a thousand times longer. The time needed for the development of a double star, or even a quadruple or sextuple system, and that required for the evolution of a stellar system or spiral nebula are at least of the same order.

In the farthest galaxies that we can observe things appear to be very much the same as in our immediate neighbourhood. There seems to be no indication that these far-away systems are in an appreciably earlier state of evolution than our own.

Although, of course, the trustworthiness of this statement decreases very rapidly with the distance, still it seems to show that the lapse of time corresponding to the distance of these systems is only an entirely inappreciable fraction of their whole lifetime. All these considerations consistently lead to the conclusion that the time elapsed since the beginning of the evolution of the universe is to be measured in billions of years, or perhaps in thousands of billions. I do not propose to discuss the question whether there ever was a beginning. It suffices for my argument to define the 'beginning' as that state of the universe and its constituent parts which we are with our present knowledge and theories content to use as a starting point, beyond which we do not wish, or are not able, to extend our investigations.

It is in accordance with this slowness of the evolution of the universe—or I should rather say of the constituent parts of the universe, its galaxies and stars—that the universe was, until very recently, generally assumed to be practically in a state of equilibrium. Accordingly a theory of the universe, in order to find popular favour, had to be static. Some may have felt inclined to disagree with this generally adopted attitude, but if they ventured to confess their dissenting views at all, they did so rather diffidently. A static solution of the fundamental equations of the theory of relativity was required. The choice was between two possible statical solutions, which I have been in the habit of calling the solutions *A* and *B*, but which may be better distinguished by the names of the 'static' and the 'empty' universe. Einstein's solution, the 'static' universe, was a genuine statical solution. The other one was essentially non-static, but, as a consequence of its emptiness, it could parade in the garb of a static one. Both of these, however, failed to represent the observed facts in the actual universe, which is neither empty nor static, since it is full of galactic systems, which are all moving with large and systematic velocities. The way out of this dilemma has been shown by the Abbé Lemaître, whose brilliant solution, the 'expanding universe', was discovered by the scientific world about a year and a half ago, three years after it had been published.

It is not necessary to explain this theory in detail here. It has become widely known by technical and popular expositions in many periodicals. The principal point of it is that it shows the observed radial motions of the spiral nebulæ to be in accordance with an isotropic, homogeneous, but non-static solution of the field equations of the general theory of relativity, or, we can say, to be a pure effect of the inertia of these bodies. The static solution, in which inertia leaves the relative distances of different material bodies (statistically) unchanged, is shown to be unstable. The actual universe must therefore be represented by one of the non-static solutions. In these the change at a certain moment may be either an expansion or a contraction. Observation shows that at the present moment we are on an expanding branch. The solutions are arranged in families. In some, the universe contracts to a finite minimum radius and then starts to expand again, in others this minimum is zero; in other solutions again the radius oscillates between zero and a finite maximum value in a rather short period. These oscillating solutions, however, require a density exceeding what is indicated by our knowledge of the distribution of matter in our neighbourhood.

I must lay stress on the fact that in using the words 'universe', 'radius', 'expansion', etc., we are really speaking metaphorically, putting an interpretation on the equations which is by no means imperative. There occurs in the equations a certain small quantity, which may be either positive, negative, or zero, and which is interpreted as the reciprocal of the square of the radius of curvature. But both this interpretation, and the assumption tacitly made that it is positive, are entirely gratuitous, and not demanded by the theory. I will, however, continue to use this convenient metaphorical speech.

Lemaître's theory not only gives a complete solution of the difficulties it was intended to solve, a solution of such simplicity as to make it appear self-evident, once it is known (like Columbus's famous solution of the problem of how to stand an egg on its small end)—it also incidentally contains the answer to some questions of long standing, such as what becomes of the energy which is continually poured out into space by the stars: it is in fact used up by the work done in the adiabatic expansion of the universe. There can be not the slightest doubt that Lemaître's theory is essentially true, and must be accepted as a very real and important step towards a better understanding of Nature.

Now if we adopt this theory of the expanding universe, it is very tempting to seek a connexion between this expansion and the evolution of the material bodies constituting the universe, and to identify the beginning of the expansion with the beginning of that evolution. But the time elapsed since the beginning of the expansion is only a few thousand million years—an interval that we have learned to consider as very short from the evolutionary point of view. There is no escape from this. We can, in fact, make the interval logarithmically infinite, but that is only a mathematical trick: we call zero minus infinity, but this does not make the interval during which anything really happens any longer. It is a consequence of Lemaître's equations that the time taken by the universe to increase its radius from anywhere near its minimum to its present value is of the order of magnitude of the radius itself, if we adopt corresponding units of space and time, for example, years for time and light-years for space.

The real origin of the difficulty is that the ratio of the natural units of space and time is determined by the velocity of light, whilst the velocities which determine the rate of progress of the evolutionary process, say in the case of a stellar system, are those of material bodies (stars), which are of the order of one ten-thousandth of that of light. Consequently, if we wish to construct a causal connexion between the commencement of the expansion and events which are supposed to have happened at a very early stage of the evolution of the stellar systems—such as the first formation of condensations, or the imprisoning of free energy inside matter called 'stagnation' by Lemaître—we unavoidably meet with the difficulty that the time elapsed since these two beginnings is some thousands of times longer in one chain of events than in the other. I do not think it will ever be found possible to reconcile the two time scales.

We thus come, however reluctantly, to the conclusion that the expansion of the universe on one hand, and the evolution of stellar systems and stars on the other hand, are two different processes, taking place side by side, but without any apparent connexion between them. The expansion has only been going on during an interval of time which is as nothing compared with the duration of the evolution. Leaving the oscillating universes, and those that start from a zero radius, out of account, the universe may have been practically stationary at or very near its minimum size for an infinite time before starting to expand, or it may have contracted during an infinite time and, after passing through a minimum a few thousand million years ago, started to expand again. In both cases there appears to be no causal connexion between the change of size of the universe as a whole and the evolution of the systems which it contains.

It should not be forgotten that all this talk about the universe involves a tremendous extrapolation, which is a very dangerous operation. I have sometimes called the part of the universe of which we know anything with certainty 'our neighbourhood'. The limits of this neighbourhood have been enormously extended in the last ten or fifteen years by the results derived from observations with the large telescopes at Mount Wilson and elsewhere, but still it is presumably only a very small portion of the whole of the universe. All assertions regarding those portions of the universe which lie beyond our neighbourhood either in space or in time are pure extrapolations. In making a theory of the universe we must, however, adopt some extrapolation, and we can choose it so as to suit our philosophical taste. But we have no right to expect it to be confirmed by future observations extending to parts now outside our reach.

The extrapolation that is at the base of the theory of the expanding universe is that our neighbourhood is just an ordinary point, or small area, in the universe, not differing from any other small area in any essential property. This is, of course, a very natural hypothesis to make, and I do not see how we can avoid making it, but it remains a hypothesis and an extrapolation. It involves, of course, the assertion—the axiomatic truth of which can scarcely be doubted by any physicist—that the laws of Nature remain the same at all times and all places. The observed fact is that the spectral lines in the light which reaches us from bodies at a great distance are displaced towards the red, or in other words, that *light is reddened by age.* Now the only interpretation of a reddening of light consistent with the accepted laws of Nature in a homogeneous world is a receding 'velocity' of the source. This is the observational evidence of the 'expanding universe' in a nutshell.

The dilemma that we are in has a certain similarity to that by which atomic physics was confronted some twenty years ago when the necessity became apparent of ascribing to the atom properties which in a finite material body would be contradictory. The concept of the universe as a closed entity is, so far as I can see, a hypothesis, an arbitrary addition to, or extension beyond, the observed phenomena by our imagination. We must be prepared to allow this 'universe', as we have been forced to grant to the atom, the freedom to have contradictory properties, and in particular we must try to accustom ourselves to the idea that the velocity of change of the quantity of the dimension of a length which occurs in the equations, and is interpreted as the 'radius of the universe', has nothing to do with the rate of evolutionary change of stars and stellar systems.

It seems to me that the current interpretation, and the consequent models of the universe as an expanding hypersphere (or elliptical space), may in course of time be found to be too simplistic, and be replaced by one in which the apparent contradictions are more satisfactorily hidden from view. But this does not affect the theory, which will retain its value, independent of the interpretations put upon it.

By Sir ARTHUR EDDINGTON, F.R.S.

DISCUSSION of detailed theories of stellar evolution is overshadowed by the fact that the time-scale is once again in the melting-pot. I think it will be agreed that if Prof. de Sitter is right in regarding the facts as indicating a rapid expansion of the universe or scattering apart of the galaxies, the very long time-scale of billions of years which has been fashionable of late becomes exceedingly incongruous: we should have to accept an age of the order 10^{10} years for the galaxies and presumably also for the stars. But the theory of the expanding universe is in some respects so preposterous that we naturally hesitate before committing ourselves to it. It contains elements apparently so incredible that I feel almost an indignation that anyone should believe in it—except myself. I have had a special reason for believing it which I have referred to from time to time, but it was not until last month that I was able to put it into definite shape.

I believe that from pure physical theory we can not only predict that this phenomenon of expansion will occur but also predict the actual rate of expansion; and the calculated result agrees with the observed recession of the nebulæ. This result comes out of the wave equation for an electron—the fundamental equation of modern quantum theory. When I adapt the wave equation to take account of the curvature of space, I find that it ought to contain a term $\sqrt{N}/R$, that is to say, the square root of the number of electrons in the universe divided by the radius of the universe in its equilibrium state.

I do not suppose that this is a new term to be inserted as a correction to the ordinary equation; it is already in the equation in disguise. It is the term attributed to the mass of the electron and ordinarily written mc^2/e^2. Sir J. J. Thomson was the first person to measure the mass of an electron. I do not think he realised in 1897 that the thing he was after—the constant which was responsible for the effects in the vacuum tubes attributed to mass—was the square root of the number of electrons in the universe divided by the radius of the universe. Really he was poaching on astronomical preserves. He was finding the rate of recession of the spiral nebulæ, or at least a very little calculation will derive it from his measures.

I take the value of $\sqrt{N}/R$ (or as Sir J. J. Thomson mysteriously called it, mc^2/e^2) according to his measurements and those of his successors, and combine it with well-known formulæ of the relativity theory which Prof. de Sitter has described; then I can find at once the principal data about the size of the universe. For example, its original radius was 1070 million light-years, before it started to expand. I find also $N = 1{\cdot}29 \times 10^{79}$; and, what is of special interest, the rate of recession of distant objects can be calculated; the result in the usual units (km. per sec. per megaparsec) is 528. This is the whole expansion effect, which will be reduced a little by the attraction of the galaxies on one another, but the reduction is not likely to be large.

The value found from astronomical observation ranges from 430 to 550 according to various determinations.

Naturally this close accordance of theory and observation has made me believe that both are right and that the observed motions of the nebulæ are genuine; so that we must accept this alarmingly rapid dispersal of the nebulæ with its important consequences in limiting the time available for evolution.

By Prof. ROBERT A. MILLIKAN, California Institute of Technology, Pasadena, Calif.

ANYONE who knows me is quite aware of the fact that I have no qualifications for participating in a discussion of the evolution of the universe, unless perhaps it be because of my interest and activity in the development of our knowledge of the cosmic radiation. Since, however, results in this field now seem destined to exert a profound, if not a determinative, influence upon all theories of stellar evolution, it may not be out of place for me to outline the present status of our experimental findings in it, and to do what I can to show whither they point.

I note first, however, that the opening up of this amazing new field of knowledge is the work solely of the experimentalist. Plentiful as theorists have always been, especially in astronomy, and confident as they have always been in their conclusions, not one of them, so far as I know, who speculated about the nature of the universe, ever predicted cosmic rays, or even dreamed of their existence—certainly not sufficiently definitely to suggest any experiments actually to bring them to light. Prior to 1910 not a trace of evidence had appeared that such rays existed. They had not even been seriously proposed. Apart from a passing suggestion by O. W. Richardson,[1] in 1906, that electroscope-discharge effects observed on earth might possibly have something to do with solar influences—a suggestion quickly negatived by the fact that these effects are as strong at night-time as in day-time —I can find no record of the existence anywhere up to 1910 of any ideas even remotely related to those of the cosmic rays. Indeed, all the work that had been done prior to 1910, even on rays capable of discharging electroscopes through metal walls centimetres, or even inches, thick (so-called penetrating rays), was generally interpreted in terms of earth-rays, or of radioactive emanations getting from the earth into the lower atmosphere, and these are, in fact, responsible for much the greater part of the then observed penetrating rays.

In 1909 all the work that had appeared in this field up to that date was reviewed by Kurz,[2] and careful consideration given to each one of the only three possible origins of the observed effects, namely: (1) the earth, (2) the atmosphere, and (3) the regions beyond the atmosphere. The last two were definitely discarded, and the conclusion drawn that there was not the slightest evidence for the existence of any penetrating rays other than those produced by radioactive substances in the earth—this with full knowledge, too, dwelt upon at length in this very article, that half a mile of the earth's atmosphere would absorb all such radioactive radiations.

When, therefore, in that same year the experimentalist, Gockel,[3] took an electroscope three different times in a balloon to heights which reached four and a half kilometres and found that its rate of discharge was there even higher than on the earth, he had discovered something new and important, namely, that although there are penetrating rays that do originate in the earth and are indeed abundantly given off from practically all the elements of the earth's crust, as Kurz and the other workers prior to 1910 had rightly concluded, yet there must be other rays, abundant at high altitudes, that come in from above, originating either in the remoter regions of the atmosphere or else coming in from outer space; in other words, that one or the other of the two alternatives which Kurz had explicitly considered and definitely discarded had been incorrectly set aside for at least some rays that actually exist. Which one of these two, namely, upper atmosphere or outer space, it took a great deal of work by Hess, by Kolhörster, by v. Schweidler, by Bowen, Otis, Cameron, myself, and others, from 1910 to 1925 definitely to determine, and even in 1927, at the Como conference, one of the most distinguished of living physicists declared himself still a believer in the theory of an upper atmospheric origin.

To-day, however, I think the cosmic origin has been generally conceded, and with that concession it follows from the measurements themselves, not only that in the particular portion of our galaxy immediately around us, the energy carried by the cosmic rays is at least a tenth[4] of that existing in the form of radiant heat and light, but also, since these latter radiations must be diminished greatly in intergalactic space, that the energy carried by the cosmic rays throughout the universe is of the same order of magnitude as, possibly greater than, all other radiant energies combined. In the light of this fact, when one reflects that the second law of thermodynamics, which has, strangely, been thought by some so determinative for theories of the origin and destiny of the universe, and which may be roughly said to be merely a generalisation of the fact always observed *here on earth* that all forms of energy tend to become converted into heat and then to be radiated away from the earth and hence lost to us, one sees *how prone we are to make sweeping generalisations upon insufficient knowledge.* This is why the experimentalist has played and always will play so important a rôle in the progress of science. From the very inception of the experimental method he has continually been bringing to light facts which were not within the theorist's ken even when that theorist had got observational phenomena pieced together, *as he thought,* into a beautifully consistent and 'necessarily related' scheme. With perhaps the largest source of radiant energy as yet unconsidered, may it not possibly be that the thermodynamic theorist has gone too far in his dicta about the origin and destiny of the universe? This is my excuse for forgetting at least for the moment all about theories and asking first: What are the experimental facts in the field of cosmic rays?

There are three main facts that now seem to be quite well established, though discussion is still rife about some of them. I hope, however, that some of the new data that I am now able to present will help to bring about better agreement.

(1) The first fact is the complete uniformity in distribution of the cosmic rays within the present limits of experimental error in the measurement of their intensity. This has been disputed by some, but I should like to show how I have been testing it this summer. I have the results of a continuous month of observation of the intensities of the cosmic rays taken through four daily six-hour periods as follows: 6 A.M. to noon, noon to 6 P.M., 6 P.M. to midnight, and midnight to 6 A.M. None of the means of intensities in these four periods differ by so much as one half of one per cent. The barometer which, as Cameron and I first showed in 1925,[5] influences markedly these intensities, was extraordinarily constant during this summer month in Pasadena, scarcely varying 3 mm. either way from the mean throughout twenty-five days; the barometer readings go through a small minimum each afternoon, due to currents set up by the sun's heat, and a small maximum early each morning. The cosmic rays, on the other hand, go through a small afternoon maximum and an early morning minimum, thus showing quite conclusively, I think, that the minute variations in cosmic ray intensities are not due to radiations from the sun, which is shining during both maxima and minima, but rather to slight variations in the atmospheric blanket induced by the alternate heating and cooling of the gaseous matter through which the rays reach the earth. Further evidence for the correctness of this conclusion is found in the fact that the period from midnight to morning, during which the atmosphere is more quiet than is the case in any of the other three periods, shows the smallest variations in the individual readings, thus appearing to indicate that these, too, are due to atmospheric disturbances. The conclusion is consonant, too, with the latest, very exact measurements of Hoffmann[6] at Halle, though the conditions in central Europe are less favourable for testing the especial points brought to light in my own work.

This independence of the cosmic ray intensities of the positions of the sun, the Milky Way, or other celestial objects is the most amazing property of these rays, since it seems to show quite definitely that those portions of the universe—better, those directions in the celestial dome—in which matter is most abundant, such as the directions of the sun or the Milky Way, have no advantage over those directions in which matter is very scarce. I can see no possible escape from the conclusion that the conditions existing in those portions of the universe where matter is abundant, that is, in and immediately about the stars, are inimical to the formation of cosmic rays. This in itself bars out the likelihood of their being due to the annihilation of protons, provided such annihilation is to be called upon, in accordance with the demands of most modern astronomers, for maintaining the temperatures of the stars. In making this statement I am eliminating as scientifically unacceptable the hypothesis that in bygone ages these rays were created by processes no longer existing and have since been wandering like lost souls about a universe from which there is for them no possibility of escape. Further evidence on this point will be presently given.

If, then, the cosmic rays are forming *now*, there is no place of origin left except *outside the stars*, in the interstellar spaces, where both temperature and pressure are exceedingly low. This is not so unlikely a place of origin as it was a few years ago, before Bowen[7] at the Norman Bridge Laboratory had solved the seventy-year-old riddle of the nebulium lines and proved that the common elements oxygen, nitrogen, carbon, and sulphur, as well as hydrogen and helium, exist out there, giving rise to these nebulium radiations *in regions which may be light-years away from the exciting stars.*

(2) The second most significant cosmic ray fact is that which, after some less precise tests by Cameron and myself in 1926, was brought to light most unambiguously just a year ago when, by taking very careful and very exact readings with the same sensitive electroscope, first at Pasadena, lat. 34° N., then at Churchill, Manitoba, lat. 59° N., the nearest settlement on earth to the north magnetic pole, I proved that the incoming cosmic rays are not influenced at all by the earth's magnetic field, and drew from that fact the inevitable conclusion that when these rays enter the earth's atmosphere they have not previously traversed any amount of matter which is comparable with the thickness of that atmosphere, or else they would of necessity be mixed with secondary beta rays which would be directed into the earth most abundantly along the earth's magnetic lines and therefore enter it in the neighbourhood of the magnetic poles. These experiments furnish another independent and, I think, very beautiful proof that the rays must originate in interstellar space, for if they came from even the remotest exteriors of stars, they would have to be appreciably mixed with magnetically deflectable beta rays. The fact that they are not so mixed seems to me to

hit the annihilation theory a second fatal blow, for there is no sort of reason for assuming that annihilation takes place *only* in interstellar space. Such an assumption would destroy the whole purpose of the annihilation hypothesis, which up to the present has been to furnish the requisite energies to the stars.

Before I leave this point (No. 2), let me combine the experimental fact of uniformity of distribution (No. 1) with this other fact that the rays enter the atmosphere unmixed with deflectable beta rays. The uniformity of distribution could indeed be reconciled with the annihilation hypothesis if it could be assumed that, in looking out from the earth into the celestial dome, one were always looking through a quantity of matter equivalent to, say, a hundred metres of water, which is a thickness sufficient to absorb 99 per cent of all incoming cosmic rays. That one would actually encounter one thousandth part as much matter as this in going out to infinity through interstellar space seems to be contrary to all the other astronomical evidence. But let us forget this and see what the cosmic rays alone have to say about this point. If annihilation is going on in all matter independently of temperature, then so far as the cosmic rays coming to the earth's atmosphere are concerned, every element of the celestial dome would be like every other element, even if the sun were in one of these elements. This is the only way the annihilation hypothesis of the origin of cosmic rays can be reconciled with their uniformity of distribution. But in this case the whole of the cosmic ray beam entering the earth would be a beam in complete equilibrium with its whole train of secondaries, including the deflectable beta rays, and these latter would of necessity spiral about the earth's magnetic lines and thus enter the earth only near the earth's magnetic poles, a behaviour which clashes with fact No. 2. Since, then, no trace of such an effect is actually found, the cosmic rays alone deny the validity of this hypothesis and with it of this form of the annihilation hypothesis as to their origin. It seems to me, therefore, that as an explanation of facts about cosmic rays the annihilation hypothesis fails at every point at which one can test it. I shall comment upon still another of its failures in the next section.

(3) The third well-established and most significant fact of cosmic rays is that *they have a banded structure.* Cameron and I first brought this fact sharply to light in 1925,[8] but I do not think the evidence is yet clearly understood or its significance fully appreciated. The evidence goes back to the high balloon flight[9] with self-recording electroscopes which Bowen and I made in 1922, a flight in which we reached an altitude of 15½ km. and got 92 per cent of the distance to the top of the atmosphere as measured by the weight of the earth's atmosphere left beneath our instruments. *In other words, remembering that the atmosphere is the equivalent of* 10 *metres of water, we were within* 80 *centimetres of the top.* Now, 80 centimetres of water allows at least 3 per cent of rays as soft even as those of thorium C″ to pass through it. We made this high flight on purpose to determine whether the rate of increase of ionisation within a closed electroscope continued exponentially to the top of the atmosphere as Kolhörster's earlier balloon flight to a height of 9 km. had indicated was the case up to that altitude. Further, Cameron and I have since, with precision instruments, obtained quite as high ionisation readings up to 5 km. as those given by Kolhörster, thus checking sufficiently his exponential curve in the lower stretches of the atmosphere; but the 15½ km. balloon flight not only failed to do this, but it showed definitely and altogether unambiguously, since all possible sources of error would have increased, not decreased, our readings, that with increasing altitude the ionisation fails to maintain its rate of increase but drops back toward lower values, just as it should do if a band of about 25,000,000-volt pure photons enters the atmosphere and requires a considerable distance of penetration into it before it gets into equilibrium with its secondaries. This furnishes a third bit of independent evidence that the cosmic rays do enter the atmosphere as practically pure photons, and hence that they originate in interstellar space.

The high balloon flight shows much more than this. It proves conclusively that neither gamma rays of energy 2,500,000 volts, like those from thorium C″, nor rays of intermediate penetrating power up to that of the softest cosmic rays, which pass through about five times as great a thickness of water and have an energy of about 25,000,000 volts, enter the earth's atmosphere in amounts appreciable in comparison with that of this softest cosmic ray band; for any such abundant rays would have very rapidly discharged our electroscope when it got within 80 cm. of water of the top of the atmosphere. In other words, there is a definite and strong cosmic ray band of penetrating power about five times (energy ten times) that of the hardest gamma rays of thorium. The analysis of this band on its other side, that is, on its short wave-length side, into much lower intensity bands but of energies of the order of 100,000,000 volts and 180,000,000 volts respectively, has been made by Cameron and me,[10] though these results are less certain. *The existence, however, of a very strong cosmic ray band at about* 25,000,000 *volts, fairly* *sharply limited on both the long wave-length side and the short wave-length side, is altogether definitely established by our experiments.* This band carries of the order of 90 per cent of the total cosmic ray energy entering the atmosphere.

Now, the experimental fact of the existence of such a band is only interpretable, so far as I can see, by the assumption of some kind of an energy-emitting atomic transformation of definite energy-releasing value taking place continuously throughout interstellar space. The other suggestions which have been made to account for a band having such energy can, as it seems to me, be quite definitely eliminated. There are but two of them. First, some kind of a cosmical electrical field has been postulated of sufficient total potential difference to impart the necessary 25,000,000 volts to electrons falling through it. There is indeed known to be a symmetrical field surrounding the earth, *but its value is definitely known to be about one million volts and its direction is such as to drive electrons out, not in; in other words, it has one twenty-fifth the requisite strength and is of the wrong sign.* No potential difference of 25,000,000 volts, symmetrical with respect to the earth and positive at its surface, can possibly be assumed without, as I think, colliding head on with other well-established facts; and even if such a field existed, it would produce a more or less continuous spectrum, like the general X-ray spectrum, instead of a well-marked band. I cannot see any way of making this suggestion reproduce even remotely the experimental situation.

The second effort has been to find a way by which rays due to the annihilation of protons (which are at least thirty-five times too energetic) could be softened down to the observed values. The most interesting of these suggestions has been made by Dr. Zwicky, who seizes upon the nebular red shift recently discovered by Hubble to suggest that if at the creation, which he estimates from the maximum possible amount of matter in interstellar space would have been about 10^{13} years ago, annihilation rays began suddenly to be formed, and if these same rays are still hurtling about in a spherical universe and are subject to the red shift, these rays, with all that have been created since, would now constitute a spectrum having a definite limit to its frequency on the long wave-length side, but falling off very slowly in intensity on the short wave-length side, where the limit would be 25,000,000 volts. In my opinion, this is the only conceivable mechanism by which annihilation rays could become reduced in energy to that observed on the long wave-length side of the band which carries nine-tenths of the energy of the cosmic rays; but the shape of the spectrum on the other side is completely wrong, since it represents a very slowly falling intensity with increasing frequency, instead of a fairly sharp, well-marked band such as experiment reveals.

No other known mechanism can soften an original beam of photons of the gamma ray type. If such a beam is in the least inhomogeneous, our universal experience is that it is hardened, not softened, by passage through matter. If, on the other hand, the original beam is monochromatic, it is also at first apparently hardened in the process of getting into equilibrium with its secondaries, and when that condition has been attained it has regained its original absorption coefficient. If annihilation rays maintain the temperatures of the stars at all, the mechanism by which they do it is not that of a continuous degradation of wave-length until the wave-lengths corresponding to heat and light waves are reached. The process is rather that the penetrating power of the beam of photons is maintained *until all of these photons have been picked off by Compton encounters* and complete absorption of the beam has thus been brought about, the temperature of the matter traversed having been thus slowly raised by this straight attrition process. Our third fact, then, of a banded structure in the particular region in which the chief cosmic ray band is found, appears to me to be the last arrow that pierces the heart of the already twice fatally wounded annihilation hypothesis of their origin.

Also, I should like to present one more reason why the hypothesis of cosmic electrical fields as an agency for directly imparting energies of from 25,000,000 volts to, say, 400,000,000 volts to electrically charged particles cannot be admitted. It is not only that the most fantastic assumptions would have to be made to make such fields produce cosmic ray bands of the type observed, but also, more than that, to make fields of any such intensities symmetrical with respect to the earth and thus account for the uniformity of distribution of cosmic rays would involve, as it seems to me, something very like a return to the geocentric theory of the universe—a return scarcely acceptable to any scientific worker who has lived since A.D. 1500.

With cosmic electrical fields and the annihilation of protons both completely unacceptable, what is then left to furnish the energy, first, of the great cosmic ray band which carries 90 per cent of the energy of these rays? The answer seems to me to be as follows:—If the Einstein equation $E = mc^2$, and the actual facts of isotopes, as accurately worked out first by Aston, are taken as guides, then this answer is unambiguous. But first, how dependable is this Einstein relation? Note first that it is a purely thermodynamic equation, stating merely energy relations. In using it, therefore, we are completely independent of any assumption as to the nature of the cosmic rays. Whether they are photons or high-speed charged particles is, so far as it is concerned, quite immaterial. Again, as to its dependability, I think that most physicists would say that it is about as safe a guide as any theoretical equation which we now have in physics. It not only rests on excellent theoretical foundations, but also it has predicted quantitative relations which have stood the tests of all the careful experiments which we have as yet been able to apply to it. *It states with entire definiteness that there is no atomic transformation whatever that can furnish the necessary energy except an atom-building process.*

I have thus far reached, merely by a process of exclusion, the conclusion that the cosmic rays are the wireless signals of the building in interstellar space of some at least of the heavier elements out of the lighter. The evidence, however, is very much better than that. It is reasonably quantitative in the case of the main cosmic ray band. Here again theory and experiment support one another. For, if atom-building takes place at all, there is one such atom-building act that is more fundamental than all others, and that also must take place more frequently than all others, namely, the formation of helium out of hydrogen, because we have abundant evidence that all the elements are actually built out of hydrogen and helium, and that helium is built out of four atoms of hydrogen, so that the hydrogen-to-helium transformation should take place much more frequently than any other. The energy of this transformation is computed from Einstein's equation and Aston's measurements at 25,000,000 volts: just what I stated above to be the energy of the large cosmic ray band that carries the great bulk of the cosmic ray energy entering the atmosphere. But the way in which I arrived at that figure requires some explanation. Most simply stated, the method used was to compare directly in the waters of high altitude lakes the penetrating power of the cosmic rays there found with the penetrating power of the hardest known monochromatic gamma rays, namely, those of thorium C″, which have an energy of about 2,500,000 volt-electrons. *This I have done directly, the observed ratio being between* 6 *and* 12.

The comparison cannot be made directly with great precision, because the cosmic rays are not homogeneous, but when the inhomogeneities are sifted out into bands (and this does not need to be done with great precision, almost any reasonable kind of sifting being satisfactory, since the softest band carries so large a fraction of the total energy) the penetrating power of this softest band comes out very close to five times that of thorium C″. Further, at altitudes between 6 km. and 9 km., where the harder components should exert almost no influence, according to the observations of both Hess and Kolhörster in their manned balloon flights, the directly measured penetrating power of the cosmic rays was six times that of the hardest gamma rays. This checks most satisfactorily with our analysis of our curve. The best formula we now have (the Klein-Nishina) connecting penetrating power and energy then makes this energy come out ten times that of thorium C″, or about 25,000,000 volts. This Klein-Nishina formula has been directly proved by Bowen and myself, as well as by others, to fit the facts up to rays of the hardness of those of thorium C″ reasonably well, and the extrapolation from there up to the softest cosmic ray band is not likely to be very badly in error. Indeed this whole procedure may be looked upon merely as the extrapolation, to a not unreasonable distance, of an *experimental* curve, and thus as largely independent of the Klein-Nishina formula or indeed of any theory. At any rate the foregoing is, in my judgment, the only quantitative test of the energy of any portion of the cosmic ray spectrum that has any sort of significance. For to use the Klein-Nishina formula to compute the energies of the rays, not five times but 200 times as penetrating as those of thorium C″, as some who have sought to make the cosmic rays proton-annihilation rays have done, seems to me to be extraordinarily rash. If my extrapolation is not significant, theirs must represent that lack of significance raised to a very considerable power.

Let me not, however, overstress the precision of this quantitative comparison. *It is scarcely necessary to do so, since there is no other energy-releasing act of this order of magnitude that can produce this soft component of the cosmic rays.* There are, to be sure, other *atom-building* acts which might produce as soft or softer rays, and some of these may well be taking place, such, for example, as the formation of carbon out of helium, but a consideration of the *abundance* of the elements involved shows that such rays would in general be of negligible intensity. The fact that there are but some five *abundant* elements is here a powerful guide.

So far I have dealt only with the formation of helium out of hydrogen. Cameron and I have shown that our complete cosmic ray curve is consistent with the existence of three other bands corresponding to the three other abundant groups of elements which we have called the oxygen group, the silicon group, and the iron group, but the evidence was here necessarily qualitative in view of two recently demonstrated cosmic ray facts. The first is that referred to above, namely, the evidence that the rays come into the earth's atmosphere as practically pure photons. For this means that we may not assume that the harder rays have reached a condition of equilibrium with their secondaries at the points at which we measure them.

The second is that interesting new fact discovered by Bothe and Kolhorster[11] a couple of years ago: that the penetrating power of the secondary beta rays may apparently, with increasing energy, rise up to, or possibly surpass, the penetrating power of the original photons. This seems to me to furnish the most simple explanation of the fact brought to light by Regener, as well as by Cameron and myself in our work at great depths in water, namely, that there is a very small component of the cosmic rays of intensity of the order of 1/500 of that of the whole cosmic ray beam as it enters the atmosphere, which has a penetrating power thirty-five or forty times that of the main cosmic ray band of which we have been speaking. The hardest rays of appreciable intensity that should be formed by the atomic building process are those of iron, and their energy should be about seventeen times that of the helium rays. There are indeed more penetrating atom-building rays that might be formed, but the abundance of the elements corresponding to them is so small that these rays should be exceedingly feeble—probably too feeble to make the formation of these heavy elements out of hydrogen a good theory as to the origin of the hardest component of the cosmic rays.

There is, however, already some little evidence, which we hope soon to complete and extend, that the penetrating power of these very hard rays increases more rapidly than does their energy, and in the present state of our knowledge this is the best working hypothesis to account for this one point which might raise doubts about the completeness of the atom-building explanation of the cosmic rays. If, however, it might be assumed that proton-annihilation does not take place in the stars, but does take place, *with* atom-building, in interstellar space, then proton-building might perhaps be called upon to account for this 1/500th part of the cosmic rays which possess this great penetrating power. In other words, if one prefers to go no further than to seek an answer to the question, What processes are able to take place in Nature that are appropriate for supplying the energy actually found in the cosmic rays? then the answer is, atom-building taking place in interstellar space for supplying more than 99·5 per cent of the rays and proton, or nucleus, annihilation for supplying the remainder. If we assume them both, then the energy-conditions represented in Einstein's equation can easily be satisfied.

The reasons, however, for such proton-annihilation in interstellar space are not so cogent as are those for atom-building. These latter reasons, apart from the direct experimental evidence, may be stated thus. We know that all the atoms are actually built up out of hydrogen, and it is therefore natural to assume, even apart from direct experimental evidence, that somewhere or other the process is going on now. Secondly, Bowen has shown that the reason so-called forbidden spectroscopic lines appear in the nebulæ and not on earth is that, given a long enough time free from collisions, an atomic change will take place that cannot take place where atomic collisions are frequent. It is not a dissimilar hypothesis, and one concordant with modern wave mechanical thinking, too, that a cluster of four hydrogen atoms *free from collisions for a long enough time* will jump over a potential wall and find themselves together in the nucleus. The reason this does not take place in the atmospheres of the stars, or even on earth, is presumably that temperature and density, that is, energy and frequency of collisions, destroy the clusters or prevent altogether their formation. But at low enough temperatures, under the influence of ordinary molecular forces, these clusters *must* form; for what is liquefaction other than the process of formation of such larger molecular groups? It is such clustering, combined with freedom from energetic collisions, which, according to the hypothesis herein presented, provides the necessary condition for occasional atom-building. It might conceivably take place in the very remote regions of our atmosphere, but in that case it should also take place in the remote regions of the sun's atmosphere; and the cosmic rays should then be much stronger during the day than at night, a result contrary to fact. Atom-building *in interstellar space* is therefore a natural enough hypothesis. Proton annihilation, on the other hand, must take place, if at all, either within the nucleus or through the rushing of an enormously energetic electron into the nucleus. These acts ought to be either independent of temperature or else facilitated by it. The first cannot be true if cosmic rays are to be explained by annihilation, else the sun would be enormously influential. The second may be true, and annihilation therefore confined to the interiors of stars as has been generally assumed. It is therefore very unnatural, if not quite impossible, to assume annihilation to take place in interstellar space and *not* in the atmospheres of the suns. This hypothesis, therefore, I should not wish to make until every other avenue of escape from our difficulties has been closed. If the ideas presented herewith prove correct, they will obviously influence strongly not only present theories but also all future theories of the origin and destiny of the universe.

By Prof. E. A. Milne, F.R.S.

It has sometimes been asked whether the universe is evolving at all. Certainly its future evolution is a matter of speculation, and its past evolution a matter of inference. But that it is evolving at this present time is not a matter of speculation at all—it is a matter of observation. We actually see stars undergoing drastic changes—changes of organisation so fundamental that they can almost be described as mutations. I refer to those outbursts which we call 'novæ'.

From time to time in the heavens a faint star is seen to blaze up for a few hours or days, increasing in brightness perhaps some twenty-five thousand times, then irregularly fading and after a few years returning to its pre-outburst brightness. Such outbursts are by no means uncommon. The first quarter of the current century has witnessed five novæ visible to the naked eye. Many will remember Nova Aquilæ of 1918, which was visible even before dark; and Nova Cygni of 1920. These from their brightness were comparatively near-by stars—Nova Aquilæ, the more distant, was only some three hundred parsecs away. But many more have been observed in the most distant regions of space. Up to 1929 more than eighty novæ had been recorded in the great nebula of Andromeda, and were used by Hubble to determine its distance. Thus novæ are distributed throughout space. They are also distributed fairly frequently in time. Hubble has estimated that some thirty novæ occur each year in the Andromeda nebula. It has also been estimated that in our own galactic system there is at least one nova per year. Such estimates are conflicting, but, as many have pointed out, they imply that every star 'becomes a nova' at least once in its life-time. We thus have in each nova an evolutionary event characteristic of the stars as a whole. Let us examine the event more closely.

The spectrum of a nova shows that the outburst is accompanied by the emission of streams or jets of gas, in various directions, at the large velocity of some 1500 km. a second. There is little doubt that this gas is a portion of the atmosphere driven off by the greatly increased radiation pressure. Some years ago when I was engaged in discussing the sun's chromosphere, I found that the hotter stars would have difficulty in retaining certain elements such as calcium, since the pressure of the outflowing radiation, greedily absorbed by the atoms in their spectral lines, would be strong enough not only to balance gravity at the star's surface, but further to repel these atoms in a kind of upward rain. Later, I examined the probable limiting velocity that such accelerated atoms would attain, and I found that it was of the order observed for the gases expelled from novæ. Thus one of the characteristics of a nova outburst is that the huge increase in brightness blasts off, almost explosively, portions of the star's atmosphere, and that these clouds of gas travel outwards through space. We shall see the evolutionary significance of this later.

This driving off of atoms probably has its maximum effect when the star is at its brightest. What of the subsequent events as the star fades ? The atmospheric layers, or some of them, continue their journey outwards, but what of the mother star itself ? Let us re-examine such a star a few years after the outburst. We find that it has returned to the same undistinguished brightness as it possessed before the outburst—but with a difference. Its spectrum is now of what is called type *O* or Wolf-Rayet, indicating a very high surface temperature or surface brightness. From this we can make a most important deduction. If the *total* brightness of the star is the same as before the outburst, but the *surface* brightness—the brightness per square mile—is much greater than before, the total area of the star must be much smaller than before. If the area is smaller, so must be the radius and the volume. The reduction in radius as observed may be as much as 10 : 1 or even more. Thus after the outburst the star is found to have shrunk. We must resist the temptation to describe it as the shadow of its former self. It is smaller in dimensions but much brighter per square mile, and as bright as before in the aggregate. We have the paradoxical situation that the outer parts expand, forming an advancing outward-moving cloud, but the inner parts contract.

We can only see the shrunken star when the expanding clouds have moved out of the way. During the outburst itself the expanding atmospheric gases obscure our vision of what is happening. We can only conjecture what goes on behind the expanding screen. But there can be little doubt as to what is actually happening. The expulsion of the atmospheric clouds is a consequence of the brightening, but the shrinking of the rest of the star is not just an accompaniment of the brightening—it is the actual origin of the brightening. When the star contracts it must lose gravitational energy, which is set free as heat and light. Somehow it must get rid of this energy. If it got rid of it slowly there would be little visible effect. Actually we see the star, in its period of maximum brightness, getting rid of an enormous amount of energy very quickly indeed.

Since the rate of brightening is very rapid, we infer that the process of shrinkage is very rapid—in fact cataclysmic. The process of shrinkage is a veritable collapse. In a nova outburst the star is seen to be collapsing on itself ; and the suddenness of the collapse, and the resulting enormous amount of gravitational energy that must be got rid of in the short time available, conspire to produce the huge brightening of the star as observed. This sudden liberation of energy produces enormously increased radiation, which in turn expels the outer layers of gas. Such is the probable explanation of the origin of novæ, or 'new stars'.

These outer layers thus expelled constitute an exceedingly small proportion of the whole mass of the star. Thus the mass of the star, after the outburst, is practically the same as before, yet it occupies a much smaller volume. Hence its mean density must be much larger than before. The increase in density as observed varies from one-hundredfold to ten-thousandfold. The gases expelled from the star during the outburst are chips from the old block ; but the star itself does not remain an old block ; it becomes very much of a new block—a very dense block.

We can now link up this widely spread phenomenon with our general views on stellar evolution. A star may be supposed to fade, very slowly but quite definitely, as it ages. At some particular luminosity it collapses, giving rise to the appearance of a nova. This must be due to some structural weakness in the star, some insecurity in its foundations. It falls on itself like a house of cards. Samson in the Old Testament story lost his strength when he was shorn of his locks. The star also loses its strength when it is shorn of its locks. But the shearing of the stellar locks—the liberation of wisps of atmospheric gases—is a consequence, not the cause, of the internal weakening.

We know other stars which are very dense—the stars which are known as 'white dwarfs' and the nuclei of the planetary nebulæ. Planetary nebulæ are probably exceptionally large ex-novæ in which the expelled gases linger round the star as a permanently accompanying nebula. It is reasonable to assume that the white dwarfs have also undergone the process of collapse—that every white dwarf has been at one time a nova. Though few white dwarfs are known, all those with which we are acquainted are close to the sun, whence it is concluded that they are very common in Nature. This is in general agreement with the ideas I am describing, since if novæ are common the heavens must be littered with ex-novæ, and these remain in the form of white dwarfs. We must now endeavour to explain the origin of the weakening which causes the cataclysm. In my investigations of stellar structure I have encountered circumstances in which this weakening occurs. There is considerable discussion at the moment as to whether stars are built of perfect gas or not. It is true that the mathematician can construct in imagination configurations of perfect gas which in some ways resemble stars, but these are not the only configurations that he can construct. We are also acquainted with another phase which gaseous matter can assume—what is called the degenerate state, a state which gases take up when the density becomes disproportionately large compared with a certain function of the temperature. Our knowledge of this state is due to Fermi and Dirac, and it was shown by R. H. Fowler that this must be the state of a very dense star such as a white dwarf.

The mathematician's task in this connexion is to construct all the configurations in which a given mass of material can occur. Similar situations arise elsewhere in physics. For example, if the mathematician is dealing with a specimen of water in an enclosure, he will find configurations in which it may be entirely steam (in a super-cooled state) or partly in the form of steam and partly in the form of water. Some of his systems will be one-phase systems and some two-phase systems. Similarly, the astrophysicist can construct configurations, of the stellar order of magnitude, in some of which the material is entirely in the form of perfect gas, in others of which it is partly in the form of perfect gas and partly in the form of degenerate gas. There are probably other phases yet unknown to us, but we can at least construct the outer parts of possible configurations. When this is done, it is clear that the two-phase configurations, having very dense cores, have enormously less energy than the one-phase configurations, and consequently that the one-phase configurations, if disturbed, will undergo a transition to the two-phase configuration. The purely gaseous configuration is analogous to the super-cooled steam, which if suitably disturbed condenses partly into drops of water. Again, it is analogous to the excited state of a Bohr or Schrödinger atom which when disturbed executes a transition to a state of lower energy, giving up the difference as radiation. In each case the excess of energy is given up suddenly. Similarly, a gaseous stellar configuration if disturbed would collapse and give up energy rapidly as it passes to a configuration of lower energy. We infer that stellar gaseous configurations are in general unstable and cannot exist in Nature. The stars in Nature must have small dense cores—a sort of foundation stone.

As the luminosity of such a star decreases, the core will vary in size. The behaviour of the core is very complicated, and I have not yet been able to trace it in full detail. But it appears that at a certain critical value of the luminosity the core increases *suddenly* in radius, due to collapse of the gaseous envelope. This is a consequence of the very low opacity of degenerate matter.

Degenerate matter obstructs the passage of radiation far less strongly than gaseous matter, and so experiences a smaller radiation pressure; accordingly, at a certain luminosity, as soon as more degenerate matter is deposited on the core, radiation pressure weakens still further, further collapse occurs, more degenerate matter is deposited, and so on. The star has a canker at the core. Or, to put it another way, degeneracy is an internal disease which propagates itself with startling rapidity under favourable stellar conditions. The outward and visible symptom of the disease is the nova-phenomenon, and, as is not unknown in medicine, a high surface temperature is developed. The existence of a discontinuity in core-radius can be established mathematically, but I only provisionally identify this particular discontinuity with the observed discontinuity in Nature. We at least obtain a hint as to the character of one of the most important events in the evolutionary history of a star.

Collapse alone is not, however, the only possibility. If the collapsing star is in a state of rotation, the increased angular velocity consequent on collapse may cause the star to divide into two, in the manner described by Jeans. This may be the origin of the great frequency of occurrence of double stars in Nature. Something of this kind has been observed in the case of Nova Pictoris. The two fragments so produced may remain collapsed (and thus very dense), or, in certain circumstances, provided as they are with an internal source of energy, they may re-expand and re-form even giant stars. In the fable the mountains gave birth to a mouse. In the heavens the dwarf may give birth to giants.

To summarise, we see a twofold evolutionary process at work amongst the stars, both parts of the process occurring in this same phenomenon of the nova. On one hand we observe the stars to be collapsing and giving birth to planetary nebulæ, white dwarfs, and even double stars. On the other hand, we see nebulous clouds driven off to space, there to reinforce the already existing cosmic cloud. Reinforce? Possibly we have struck the real origin * of the cosmic cloud—possibly the cosmic cloud is the totality of the debris of the expelled atmospheres of novæ and other hot stars. The universe is simultaneously condensing into hard blocks and evaporating to form a tenuous nebula. I repeat, this is what we observe. Sir James Jeans has suggested that the universe began as a widely-extended nebula, which condensed into stars in virtue of gravitational instability. The picture I have attempted to draw is that of a concourse of stars, on one hand condensing into denser stars in virtue of instability under a waning light pressure, and on the other hand simultaneously expelling their atmospheres and generating a nebula.

---

* This idea has been suggested also by Vorontsov-Velyaminov, *Observatory*, Aug. 1931.

By General the Right Hon. J. C. Smuts, P.C., C.H., F.R.S.

In a sense my presidential address dealt with some aspects of the evolution of the universe, but a good deal more could be said, if there were time, about the philosophical issues which are raised by this subject.

I do not agree with those who say that the recent advances in physics have no important value for philosophy. The most creative philosophical thinkers in the past have as a rule been saturated with the science of their time, which gave substance and body to their philosophy; and it is only to be expected that the recent revolutionary advances of physics are bound to have the most profound effect on our world-view and on our philosophical outlook. How, for example, could philosophy, which has for thousands of years speculated on the nature of time and space, be unaffected by the fruitful integration of the two which has been effected by the physicists in our time? Again, the concept of the quantum, with its peculiar behaviour, its holism, its indeterminacy, is bound to be far-reaching for philosophy no less than for physics. Of course, it is extremely difficult at this early stage, when we are at the beginnings of these changes and physical theory is still in a state of flux, to say what exactly will be the philosophical outcome of the new physics. But I have little doubt that the revolution in physics will yet be followed by a revolution in philosophy, and that in their joining of forces a new era will open up for both science and philosophy.

So far as philosophy is concerned, one is at present perhaps more impressed with the difficulties and perplexities, arising from the new concepts in science, than with its solid results. Thus one is inclined, from the point of view of relativity, to attach the greatest importance to the new space-time concept. If the old forces of Nature, like gravitation, and perhaps even electromagnetism, are (as Einstein teaches) nothing but curvatures of space-time, if matter itself is really only such a curvature, one feels inclined to look upon space-time as the basic structure of the world, and as no mere mathematical symbolism. Space-time becomes something like the old ether, a substratum or matrix from which all the physical differentiations have taken place. To such a view one is inevitably led by the relativity theory and its results. Yet the next moment, when one considers the behaviour of the ultimate physical units, especially the electron and the quantum, one meets with phenomena in flagrant contradiction with the idea of space-time, as if, for the electron and quantum, space and time really do not exist, as if space-time is a macroscopic result rather than an ultimate basic feature of the cosmos. If space-time is merely a statistical macroscopic result, there seems to be some flaw in the fundamental relativity treatment which makes it basic to everything in the world of existence. We seem to be making for a real clash between the relativity and the quantum concepts, unless we have to admit that both are still provisional, and that a wider, truer unification or reconciliation is still to come.

I could refer to other difficulties and perplexities arising from the new physics, but I pass on to another point which has perhaps a closer bearing on our topic for discussion. I wish to refer to the peculiar character of the ultimate physical units and their bearing on the evolution of the universe. Many physicists, including even a profound thinker like Sir Arthur Eddington, maintain the view that exact science, and physics in particular, is confined to the metrical aspects of the world and has nothing to say as to the nature of the universe. If this is really so, then how could Sir James Jeans say, in a recent book of his, that the universe as viewed by the new physics is more like a great thought than a great machine? This seems to go far beyond the metrical characters of the world. If physics were confined simply and solely to the metrical aspects of the world, then how can Sir Arthur Eddington himself find intimations of freewill in the law of indeterminacy? Truth is a whole, and the truth of physics will be found to link on and to be but part of that larger truth which is the nature and the character of the universe.

When we speak of the evolution of the cosmos we are faced with a series of questions in regard to the ultimate physical constituents of the world and their interplay, the routes they follow, the structures they form, and the resulting characters, size, mass, and properties of the universe as a whole. These are problems for physics. But we find that that evolution also comprises the emergence of life and mind, of the human soul and human personality, and a whole new world of values of all sorts. Truth, beauty, goodness, and love are as much structures of the evolutionary universe as the sun and the earth and the moon. But when we come to scrutinise the ultimate foundations of this vast superstructure, we naturally look for the characters which would in the long run render such enormous developments possible. This would be in particular the attitude of the philosopher, with his wider outlook over the realms of existence; and it is for him that from this point of view the new quantum physics has a peculiar fascination. For he finds that the physicists, working merely with their own tools and their own incomparable technique, and looking for no more than the metrical units which subtend this universe, have indeed, like the man who looked for asses and found a king, found much more than they have looked for. The units they have discovered will constitute not only a world of physics but, in the end and at far removes, also a world of life and spirit.

These units, particularly the electron and the quantum, have an almost metaphysical aspect: they are physics infected with thought; they are not in space-time, they behave as wholes, they are indeterminate in their behaviour, so that the law of chance rather than the ordinary causal law applies to them. Of course, it is possible that this ambiguous character is due to infection from the mind of the research worker, as if the mental instrument of research has affected the result. But it is far more likely that in this dual character of the physical units we reach an ultimate basic fact, that we transcend the mind-matter distinction and reach the bedrock where no such differentiation has yet arisen. Thus it comes that the ultimate units are not purely physical or material, but point to an undifferentiated primitive world matrix, which includes both the physical and the thought characters of the world.

When from these units we start our process of world building, we find at first what is apparently merely a physical universe. But gradually the suppressed vital and mental elements, inherent in the universe from the start, begin to emerge. Cosmic evolution is thus found to include organic evolution, and this again gives rise to the evolution of spirit, of social and spiritual values, which form our own human phase of this cosmic process.

The origin of life from matter, of mind and personality from both, has always seeemed an unresolvable mystery. The philosophy of emergence which has recently arisen, and purports to explain the creative rise in evolution, the coming of life and mind and spirit—this philosophy has appeared to be based on a miracle or a series of miracles. The quantum physics has come to the relief of this school, which surely teaches a significant truth. According to quantum doctrine, the roots of life and mind lie imbedded deep down in the ultimate structure of this universe, and they are not mere singular apparitions of an unaccountable character, arising accidentally in the later phases of evolution.

To me the significance of the new physics for philosophy seems to lie particularly in this linking of the deep-down beginnings with the most advanced achievements of the universe. The apparent huge gaps in evolution, requiring a miracle of leaps at more than one stage, are thus shown to be a gross exaggeration. We see the universe gradually pushing to the front certain features and characters which have been there all the time from the very beginning, although in most primitive and scarcely recognisable form.

One concluding remark. We cannot say that the universe has been built up from these units or any ultimate units in the course of its evolution. We can only say that these are the ultimate elements which we find on analysis. The universe may for ever have been a complex affair, a closely knit structure of some sort or other, as the law of entropy would seem to indicate. It may even have been one vast quantum, as the Abbé Lemaître suggests. But in the evolution of this mass there has been relative movement of parts or features; some have pushed more to the fore with time, and there is no doubt that life and mind are features that have thus emerged from the mass, with the increase of entropy.

By the Right Rev. E. W. Barnes, F.R.S., Bishop of Birmingham.

I will begin by briefly recapitulating the theory of the evolution of the universe in the form in which, as I understand, it at present exists.

In the beginning, a large unbounded finite three-dimensional universe with space of very small positive curvature was filled with highly diffused matter of very small density. The matter began to aggregate into masses of approximately equal size, spread fairly uniformly throughout the space; and the whole space began, at some epoch or another, to expand. The masses attracted neighbouring matter and somehow acquired velocities of rotation which increased as the matter in them condensed. Finally, incredibly vast bun-shaped aggregates, spinning too quickly for the stability of their outer edges, began to throw off drops, as it were. The drops congealed into suns, and ultimately the aggregates became the spiral nebulæ which now exist. Each of them, apart from possible central regions of diffuse matter, consists of thousands of millions of stars. Our sun is a star of no particular importance, belonging to a spiral nebula or group of nebulæ called the Galactic universe. That universe came into existence some five million million years ago.

Since they first existed, stars in the various universes have moved aimlessly under the influence of their initial velocities and mutual attractions. Periodically, but rarely, at intervals of tens or hundreds of millions of years, collisions between suns in the various universes have taken place and planetary systems have been born. So the earth came into existence some two or four thousand million years ago. Thus ours is quite possibly one of the youngest planetary systems in *our* universe. On the cooling earth primitive forms of life appeared at least a thousand million years ago; and gradually, by a slow evolution, more highly developed living organisms arose. Finally, about a million years ago sub-men emerged from a group of anthropoid apes.

If I personally am critical of this picture, I plead that we must not confuse speculative possibility with satisfactory demonstration. I am concerned that we do not give arguments to obscurantists, who claim that the scientific theories of one generation are usually repudiated by the next. So I would begin by emphasising that in the group of possibilities and probabilities just outlined there is much less certainty than, say, in the facts upon which Darwin rested his conclusions when the "Origin of Species" was published seventy-two years ago.

I need not refer to the prejudiced opposition by which Darwin was assailed. Of course, his triumph has been signally complete. But others before him had put forward theories of the evolution of terrestrial animals. What Darwin did was so to accumulate and arrange biological facts, that experts were convinced that evolution by the mechanism of natural selection had produced from primal organisms the vast range of living things upon the earth, including man himself. Since Darwin wrote, further investigation and discovery have confirmed his insight. Some of his subordinate opinions were erroneous ; but his main scheme stands intact because his facts were correct. All fresh geological and embryological investigation confirms the conclusions on which he rested. The scanty remains of primitive man that are discovered from time to time accord with expectation ; and such statistical investigation as those in R. A. Fisher's recent volume are a triumphant vindication of the potency of natural selection.

It is worth while recalling these facts when we consider the picture of the evolution of the universe which has emerged from recent work. I personally doubt whether the time has yet come for an astrophysicist of genius to write a book which shall in its own sphere rival the "Origin of Species". We can point to a few new facts and to considerably more new (and occasionally discordant) theories. Out of them there has emerged the present picture, immensely exciting, but by no means certain.

What of it can we regard as certain ? First of all, there is no reason to doubt the existence of island universes. Such form that vast, fairly regular distribution of spiral nebulæ through the depths of space which is revealed by photographs taken in the great telescopes. We can say with fair certainty that our own galactic universe is either a single spiral system or an aggregate of several such, each analogous to millions of others with which space is strewn.

Secondly, I would say that it is fairly certain that our space is finite, though unbounded. Infinite space is simply a scandal to human thought ; and, though we must not assume that the universe was made that man might understand it, the alternatives to finite space are incredible. We cannot accept the idea of island universes succeeding one another indefinitely as we pass in imagination through the depths of space. Such a distribution does not accord with a Euclidean-Newtonian gravitational scheme, for it would lead to infinite gravitational potentials. Neither can we with equanimity think of a vast finite group of universes forming a sort of island in empty space. Ultimately such a group ought, one would surmise, to aggregate into a single mass. But in Riemannian spherical space we can have a finite and uniform distribution of universes, inasmuch as such space is unbounded so that every point is related to the whole as is every other point. Finally, there is no fact of observation to set against the belief that space has a very small positive curvature.

Thirdly, I think we must accept as highly probable Jeans's hypothesis that in the stars matter is actually destroyed as protons and electrons unite to form radiation. To this conclusion, however, we are driven by failure to find any satisfactory alternative explanation of the vast output of energy by the stars. If, however, their lives were not to be measured by so long a period of time as millions of millions of years, the necessity for assuming the actual destruction of matter would not be so great.

Consider now some of the uncertainties and difficulties which belong to the present scheme. First of all, of course, there is the insoluble difficulty of infinite time. No man of science will postulate a supernatural intervention, a stirring of the uniformly distributed matter filling space with which in imagination the present scheme begins. Yet in default of such a beginning, we must imagine an infinite regress, a never-ending sequence of alternate periods of world-building and world-destruction, the rise and fall of universes without end. In comparison with such a past the future is perhaps less perplexing, though it is not very satisfying, because the second law of thermodynamics seems to necessitate an end when all energy will have so run down that nothing happens anywhere to break a deadly uniformity. Of course, we can escape from the difficulties caused by infinite time if we accept the opinion entertained by some philosophers that time is not real. With them we may hold that the notion of time is due to the nature of our perception. If we accept such an idea, we can assert that consciousness in its passage through the space-time continuum meets but does not cause events. It then follows, however, that all our fancied activities are an illusion. Against any such belief we must put what surely is our constant and invariable experience. We *have* a measure of freedom of will. Labour and struggle *are* real. We *can* get nearer truth and overcome evil as we strive for goodness. Thus I am forced to conclude that the time-process must be real. Yet, unless time is an illusion, or unless alternatively the cosmos had a beginning in time, any picture of the evolution of the universe must fail to satisfy.

Let us take it, however, that the primal mist that filled all space in the beginning aggregated into masses of roughly equal size in a finite universe and that these masses slowly began to condense and revolve. Whence came their rotation ? To this question I can find no satisfying answer. Let us ignore the difficulty. Out of condensation and rotation came the spiral nebulæ, the universes of thousands of millions of stars with which space is strewn. Obviously, with relatively few exceptions, the great nebulæ are built to a common pattern. They are results of rotation, and the picture of vast rotating lenticular masses throwing off stars, like drops at the edge of a fly-wheel, satisfies the imagination. But why are the arms of the spirals so short ? We should expect arms which curl repeatedly round the central nucleus. None such exist ; and yet there is apparently no ejection into space of early-born stars to account for the disappearance of the coils of stars that ought to be visible.

The different chains of reasoning by which Jeans has been led to assign a period of millions of millions of years for the age of our universe seem to me to demand respect. I doubt whether they are conclusive. But I wish that there were certain knowledge of the development and decay of typical stars. Theories abound. Some are magnificent in the ingenuity and in the intellectual power which have gone to their making. But the final theory of stellar evolution has not emerged. I confess, moreover, that I am by no means happy with regard to the expanding universe, and I doubt whether Doppler's principle is rightly applied to measure the velocities of recession of the great nebulæ. It is not improbable that the reddening of their light is due to other causes If the great nebulæ are moving away as fast as is suggested, we are lucky to be living at an epoch when we are able with our telescopes to see them at all. Moreover, the Friedman-Lemaître equations give contraction as an equally possible alternative to expansion. May it not be that a velocity of approach is masked by some other effect ? A universe that was continuously contracting would have a snug end. Steady and continued inflation, either of a currency or of a universe, is disquieting.

It is, however, when we come to the formation of planetary systems that I feel especially uneasy. The current theory is, as I have said, that the earth and its associated planets arose from the encounter of our sun with a wanderer which came so near as to disrupt it some few thousand million years ago. If the theory be true, planetary systems must be rare and therefore consciousness, as men know and possess it, is rare. In fact, the existence of consciousness, when it occurs, will be the by-product of an accident. We are then apparently forced to conclude that the universe was not created with the primary object of producing beings in whom mind should lead to spiritual excellence.

There is, of course, no reason why consciousness should be associated with animals such as ourselves who represent transformations of carbon compounds at temperatures between the boiling and freezing points of water. It might, for all we know to the contrary, be associated with changes in the ionisation of atoms or with the disintegration of their nuclei at temperatures of hundreds of millions of degrees. But of any such bases for the appearance of mind we have no knowledge. What we do know with certainty is that throughout the universe the raw material of which it is made is fairly uniform. The matter in distant stars is the same as that which exists in our own sun. We must then assume that there are planetary systems in distant island nebulæ, and that on some of them conditions resemble those which exist on our earth. So life, as we know it, must be distributed throughout the universe; but, if the collision theory of planetary origins is correct, the distribution is astonishingly sparse.

I do not, of course, suggest that there are human beings on other planets. The direction of the physical and physiological evolution of living things upon our earth would seem, if we can judge by the geological record, to have been somewhat erratic. Particular mutations coincided with particular conditions of environment to determine the direction of change at any instant. But, throughout the known geological process there has been large-scale progress, a possibly unsteady but quite definite development of mind. In the possibly very different living organisms of other planets there will have been a progressive development of mind. Our physical structure matters little in comparison with the kind of consciousness which it carries.

We can then, as it seems to me, assume the existence throughout the universe of conscious beings. If it be true that our earth and all planetary systems similar to our own originated in a chance collision of suns, life elsewhere must be as a rule unimaginably more developed than with ourselves. Also planets carrying living organisms must be incredibly rare. After a life history of five million million years our galactic universe will have but one sun in a hundred thousand with satellites which can carry life. Such extravagant world-building for such meagre results leaves one dubious as to whether the theory is correct. In defence of such doubts as are forced upon me I might point out that the origin of our moon, with its exceptional density and massiveness, has not been finally settled. The theory that it was broken from the earth when the latter was mainly liquid owing to a chance 'resonance' phenomenon Jeffreys, in a recent paper, deems untrue. Even present estimates of the age of the earth, in so far as they depend on the rate of disintegration of uranium, puzzle us because we do not know why there should have been any uranium in the earth at its birth. Thus I personally should not be surprised if new facts were forthcoming to give some other explanation of the existence of planetary systems. I suspect that such systems are much more numerous than is at present believed.

I need scarcely emphasise that the issue raised by the relative frequency of planetary systems is of great philosophical importance. From Judæa, through the Christian church, has come a belief in ethical theism which has been a strong and ennobling influence in European civilisation. To-day such belief rests upon the conviction that we can only explain the universe by assuming that it is due to creative thought and will, associated with purpose and plan. Such purpose appears most clearly on earth in the progressive development of mind, which has ended in the recognition of moral values by humanity; and the religious outlook of many of us is determined by our belief that God has thus created man for His service. But, if consciousness should be proved to be but a rare accident of a vast, otherwise aimless, universe, such belief in God would be encumbered by a new perplexity. I may add that the belief would not disappear, since we should still have to explain why man has been created with the conviction that he must be loyal to goodness and truth.

Such philosophico-religious speculation is, however, premature. We need more facts and, that we may obtain them, we need new instruments of greater power and precision. The interferometer, we may hope, points the way to instrumental triumphs in the future. If only an instrument could be invented which should enable us to determine whether stars, within, say, a hundred light-years' distance, have planetary systems attached to them! We should then know whether any of the few thousand stars near the sun have planets on which life may conceivably exist. If even one such system were found, the present theory of planetary origins would collapse. Failing any such invention of a super-telescope, there remains the possibility of wireless communication. As I have already indicated, I have no doubt that there are many other inhabited worlds, and that on some of them beings exist who are immeasurably beyond our mental level. We should be rash to deny that they can use radiation so penetrating as to convey messages to the earth. Probably such messages now come. When they are first made intelligible a new era in the history of humanity will begin. At the beginning of the era the opposition between those who welcome the new knowledge and those who deem it dangerously subversive will doubtless lead to a world war. But the survivors, when they extricate themselves from the economic consequences of the peace treaty, will begin what we may correctly term a strenuous correspondence course. I should like to be living then. We might get a true understanding of the evolution of the universe.

By Sir Oliver Lodge, F.R.S.

It is well known that a physical theory which ignores some of the elements of the problem is incomplete, and is therefore liable to break down when confronted with the facts. A physical theory cannot take the whole universe into account; but if it is to be complete enough to be satisfactory, and to make trustworthy predictions, it must take all relevant factors into account.

Sir James Jeans began his discourse by saying that in Section A we were concerned only with the physical universe—that is, with material bodies and the forces that act upon them. I suppose that is true. But the fact that it is true seems to make it impossible for this Section to enter upon a philosophical discussion of such a subject as the universe as a whole, and to decide its fate upon purely deterministic lines. For the universe certainly contains more than we deal with in this Section. We must remember that there are Sections D and K and I and J—that is, we must realise that the universe is not solely inorganic. Some of the matter is animated; and although it is still obedient to the laws of physics and chemistry, an animated body behaves in a spontaneous manner not predictable by those laws. When a thing behaves as if it were alive, physics loses interest in it and hands it over to another section; for it is incompetent to deal with motions attributable to spontaneity and free will. Wherever life has entered in, the predictions of physicists and astronomers and mathematicians are spoilt. Laplace's calculator might reckon the behaviour of every particle in the universe so long as it was not interfered with by life and mind.

I have looked sometimes at the ripples coming over the sand on a sea beach and leaving a deposit of foam. I have thought whether a mathematician, given sufficient data, could predict every ripple and every line of foam. Yes, he could, theoretically, provided there were no boats, nor any fish. The splash of a fish, the ripples of a boat, would put his calculations out. Given even a spark of free will, there are no data that can be supplied. It may be said that our sense of free will is an illusion. Well, that is a philosophical question that can be raised. But it cannot be settled in this Section. So I venture to think that before we can philosophise upon such a theme as the ultimate fate of the universe, we must be able to take everything into account, and philosophise with a very wide and comprehensive knowledge of reality.

Maxwell showed how the effect of mind could be introduced into the scheme of physics without contravening any of the laws of energy, except the purely statistical second law of thermodynamics. His 'demon', by dealing with the particles individually and selectively directing them, could interfere with and neutralise the consequences supposed to be deduced from that law. I claim as a physicist that too much attention has been paid to this second law of thermodynamics, and that the final and inevitable increase of entropy to a maximum is a bugbear, an idol, to which philosophers need not bow the knee.

It is doubtless instructive to learn from high and competent authorities what the unadulterated or rather unvivified laws of physics applied to the universe will lead to. We are faced with a steady running down or degradation of energy to a predetermined end: without hope of novelty introduced at any stage of the process, all settled and dull, events just going through the hollow form of taking place. But it is all on the assumption that there is nothing or no one to wind it up or to guide it to some nobler end. Guidance has only recently intruded itself into the scheme of physics; but already there are guiding waves which determine the path of a particle of matter. What the significance of those guiding waves may be, whether they have any connexion with the observed phenomena we know as life and mind, is at present an unanswered question.

To philosophise from a restricted point of view is interesting enough, but it is not conclusive. It does not fully account for the state of the world to-day, nor can it be depended on to formulate its course to-morrow.

deposits; major divisions of the Palæozoic; geomorphogenic processes in arid regions; fossil man and contemporary faunas; and orogenesis. It is also hoped to make provision for the presentation of papers not falling under any of these headings. The responses received, together with those from the first circular, will form the basis of the mailing list for the next circular. This will be issued in 1932 and will contain registration forms. The present circular may be obtained from the General Secretary, Sixteenth International Geological Congress, Washington, D.C., to whom all inquiries should be addressed.

SIR SIDNEY HARMER, lately Director of the Natural History Departments of the British Museum, has been elected a foreign member of the Royal Swedish Academy of Science.

AT the ordinary meeting of the Institution of Electrical Engineers to be held on Nov. 5, an oil painting of the late Dr. S. Z. de Ferranti, an honorary member and a past president of the Institution, will be presented to the Institution by Mr. H. Marryat. The portrait is by Mr. David Jagger, R.A.

THE following have been elected officers of the Philosophical Society of the University of Durham: president, Prof. R. A. Sampson; vice-presidents, Sir Westcott Abell, Prof. G. R. Goldsbrough, Prof. T. H. Havelock, Prof. P. J. Heawood, Sir William Marris, Prof. J. Irvine Masson; honorary general secretary, Mr. W. M. Madgin; honorary treasurer, Mr. J. W. Bullerwell; editor, Prof. G. W. Todd; and honorary librarian, Dr. F. Bradshaw.

ON Oct. 13, the first public lecture under the Estlin Carpenter Educational Trust was given at Oxford by Sir Peter Chalmers Mitchell, on the subject of "Life and Matter". The chances, he pointed out, are enormously against the existence of requisite conditions for life elsewhere than in very minute parts of the universe. In support of the view that life is not a distinct principle apart from physical and chemical conditions, Sir Peter laid stress on the facts now known concerning the properties of crystals, of colloids, and of 'Bütschli's foams'. Speaking of the production of organic substances in the laboratory, he instanced the formation of starch and sugar from formaldehyde under the influence of ultra-violet rays. Much advance has been made in this direction since the first artificial production of urea.

AN autumn expedition to Churchill, on Hudson Bay, for the purpose of photographing the aurora borealis is announced by the press bureau of the Canadian National Railways. Churchill has been chosen because it is in the direct line between the auroral and the magnetic poles and on the path of the maximum light frequency of auroral waves. The expedition, which is now at work, will remain for about six weeks, and hopes not only to photograph the aurora but also to measure its height. In order to record the complete range of colour in the aurora, special cameras have been designed.

THE Ministry of Health desires to continue the investigations, commenced in 1926, into the characteristics of acute disease of the nervous system (occurring in the form of meningitis, encephalitis, or polio-encephalitis) following in the wake of vaccination or of acute infections, such as measles, chickenpox, influenza, and the like. It is therefore requested that medical practitioners who may be called in to attend cases of this nature will immediately forward information to The Senior Medical Officer, Med. i., Ministry of Health, Whitehall, London, S.W.1. Attention is also directed to the fact that an antivaccinal serum has been prepared by the Lister Institute, doses of which can be supplied by the Ministry on application, for the treatment of post-vaccinal encephalitis.

THE twenty-second annual exhibition of electrical, optical, and other physical apparatus is to be held by the Physical Society and the Optical Society on Jan. 5–7, 1932, at the Imperial College of Science and Technology, South Kensington. The Trade Section will comprise the exhibits of manufacturing firms. The Research and Experimental Section will be arranged in two groups: (*a*) exhibits illustrating the results of recent physical research; (*b*) lecture experiments in physics. The Exhibition Committee invites offers, from research laboratories and institutions and from individual research workers, of exhibits suitable for inclusion in either of the above groups. Offers of exhibits, giving particulars of space and other facilities required, should be communicated immediately, and in any case not later than Nov. 9, to the Secretary, Exhibition Committee, 1 Lowther Gardens, Exhibition Road, London, S.W.7. The Section for Apprentices and Learners has for its object the encouragement of craftsmanship and draughtsmanship in the scientific instrument trades. Apprentices and learners may exhibit, in competition, specimens of their work, providing they are in the regular employ of a firm which is exhibiting at the next annual exhibition, or has exhibited once during the past three years. Printed particulars of this Section will be sent on application to the Secretary.

A SHORT list (S.S. No. 2) of second-hand scientific journals, transactions of learned societies, and books relating to science has reached us from Messrs. Oppenheim and Co. (Rare Books), Ltd., 317A Fulham Road, S.W.10.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A graduate assistant master for mathematics, science, etc., in the Devonport High School—The Secretary for Education, Rowe Street, Plymouth (Oct. 31). An engineering assistant in the water department of the City of Sheffield—The General Manager and Engineer, Town Hall, Sheffield (Oct. 31). A graduate assistant in the mathematics department of the Coventry Municipal Technical College—The Director of Education, Council House, Coventry (Nov. 12). A science master at Sir Thomas Rich's School, Gloucester—The Headmaster, School House, Gloucester. A senior mathematical master in the Newport, Isle of Wight, Secondary School—The Director of Education, County Hall, Newport, I.W.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Age of the Oldoway Bone Beds, Tanganyika Territory.

As readers of Nature are aware, there has been a certain amount of controversy over the Oldoway skeleton found by one of us (Prof. Hans Reck) at Oldoway, in Tanganyika Territory, in 1913.

In order to clear up this question if possible, and to try to find some data by means of which the Oldoway bone beds could be definitely correlated with those in Kenya Colony, it was decided that the East African Archæological Expedition should spend a part of the 1931–32 season at Oldoway, and Prof. Reck (of Berlin) and Mr. Hopwood, of the British Museum (Natural History), were invited to be members of the expedition during that part of the season's programme.

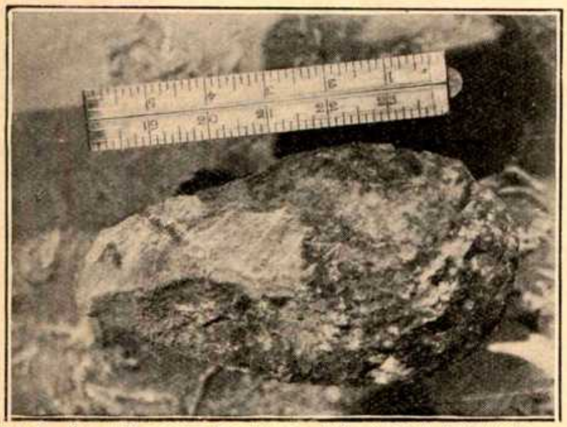

Fig. 1.—One of the coups de poing found *in situ* in Bed B at Oldoway.

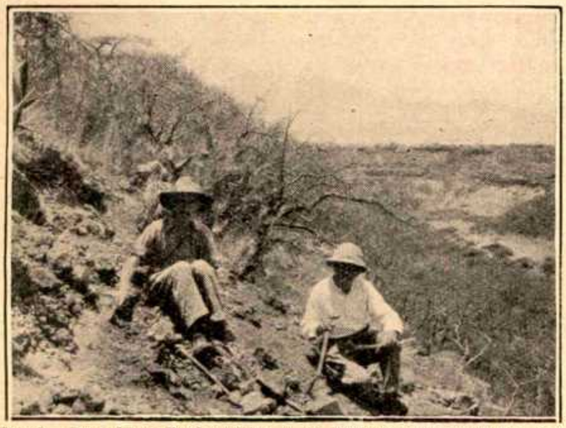

Fig. 2.—Prof. Hans Reck and Mr. A. T. Hopwood sitting on the exact spot where Prof. Reck dug out his Oldoway man in 1913.

After a very careful examination of all the evidence on the spot, and the collection of certain new data, we have come to the following conclusions:

1. There is no possible doubt that the human skeleton found in 1913 came from Bed No. 2, and not from a pocket of Bed No. 4, as was suggested by one of us (Leakey) in "The Stone Age Cultures of Kenya".

2. Beds Nos. 3 and 4, which overlie Bed No. 2 conformably, have both yielded unrolled coups de poing *in situ*, and these tools are absolutely typical of the late Kenya Chellean and of the Kenya Acheulean from the upper part of the Kamasian series at Kariandusi River, as described in "The Stone Age Cultures of Kenya" by Leakey. Bed No. 2 has so far yielded two flakes with definite bulbs of percussion.

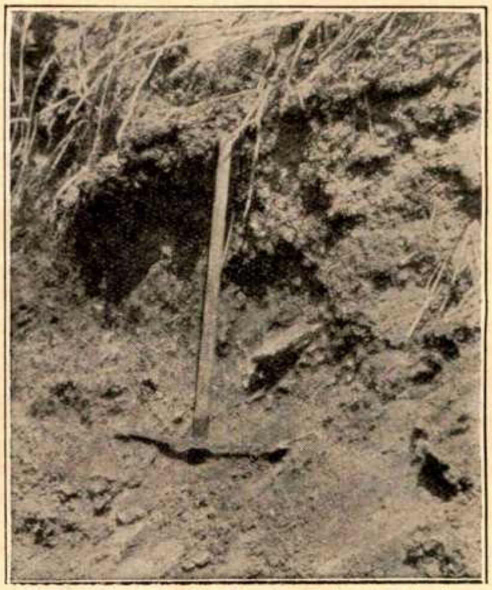

Fig. 3.—The same coup de poing as Fig. 1 but *in situ*.

3. Although in Kenya the deposits of Kamasian age have yielded as yet no identifiable fossils, it thus seems to us clear that the Oldoway bone beds are the equivalent of the Upper Kamasian, and this correlation is borne out by the fact that the Oldoway beds, like the typical Kamasian series in Kenya, are older than the period of volcanic activity and rift faulting, which was responsible in Kenya for the Gilgil and Kikuyu Escarpments and the volcanic mountains, such as Longonot, Suswa, etc., and in Tanganyika Territory for the Ngorongoro volcanic highlands and the escarpment which cuts them to the east.

4. The fact that the Oldoway bone beds prove to be of Upper Kamasian age and not Gamblian is absolutely in harmony with the palæontological evidence, since the Oldoway beds contain a fauna in which more than 50 per cent of the animals are extinct genera and species.

5. From all the available evidence, it thus seems to us that the Oldoway skeleton represents a type of *Homo sapiens* living during the Upper Kamasian period, from which up to the present the only lithic cultures known are the late Kenya Chellean and the Kenya Acheulean.

The Mercury Band Spectrum in Fluorescence.

Much has been written on the various band-series and isolated bands in the spectrum of mercury, and their relation to the atomic excited states: but it cannot be said that the subject has been satisfactorily cleared up.

I wish here to record an observation which will help to decide between the various alternatives which have found favour. Mercury vapour saturated at a pressure of 5 mm. was excited to fluorescence by a cooled mercury vacuum arc, the light of the latter being filtered by a dilute solution of thiophene in alcohol, which completely cuts off wave-lengths of 2460 or less. Under these conditions the fluorescence is excited exclusively by the core of the atomic resonance line. I have called such fluorescence the 'core effect'. The spectrogram shows the first three members of a series of bands originally found in absorption by R. W. Wood. These are at 2345, 2338, and 2334. Being of much shorter wave-length than any line from the thiophene-filtered source, the bands appear on a clear background free from false light. I do not know of any equally striking case of the violation of Stokes's law.

As regards interpretation, I limit myself at present to remarking that the experiment suggests a relation of Wood's bands to a ^3P and not to the ^1P state of the molecule. It would be easy to say a good deal more: but there has perhaps been a tendency to over-facile theorising on this subject, and further discussion is reserved.

Constitution of Thallium and Uranium.

THE preparation by Dr. v. Grosse of suitable volatile compounds of thallium and uranium has enabled me to obtain their mass-spectra. The lines of thallium were obtained by means of its triethyl compound. As was expected, it consists of two isotopes, 203, 205. The latter predominates to an amount in good agreement with the chemical atomic weight (204·39).

Results with uranium hexafluoride indicate that uranium is probably simple to at least 2 or 3 per cent. Its line 238 was photographed in satisfactory strength, followed by a series, 257 UF, 276 UF_2 . . . etc. The last line visible in this series, 333, corresponding to UF_5, is the heaviest mass definitely recorded on a mass-spectrum. It has not yet been possible to determine the packing fraction of U 238.

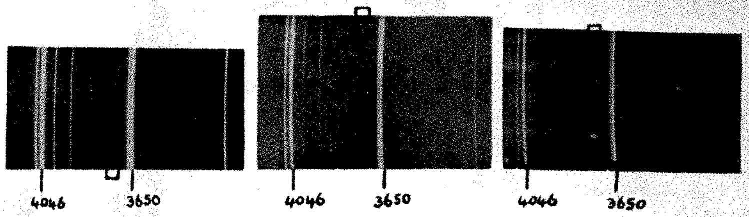
Raman Lines due to Co-ordination Bond.

FOLLOWING J. J. Thomson, Kossel, and others, it can be shown that a large number of observed facts about co-ordination compounds can be explained on the assumption that these groups are held by purely electrostatic forces to the central atom. Grimm has been able to calculate the heat of association per molecule of NH_3 surrounding the cation of a simple salt, from a knowledge of the heat of formation of the ammines and the lattice energy of the simple salt. He has shown that for a monovalent cation with an octet shell the heat of association is 14 calories per gram molecule, 28 calories for a divalent ion, and so on. Also, the maximum co-ordination number of an atom can be shown to depend on the relative size of the latter to those of the co-ordination groups.

Other properties of such compounds, namely, the diamagnetism of certain complex radicles with a paramagnetic central atom, the change of valency of the radicle when one of the co-ordinated group is replaced by another, for example, by the replacement of a NH_3 group by Cl, find an easy interpretation on the theory proposed by Sidgwick. According to this theory, the co-ordinated groups are bound to the central atom by homopolar bonds, in which both the electrons are supplied by the former. It has been pointed out by one of us [1] that from magnetic evidence alone it can be shown that even in the case of co-ordination compounds of the iron group of elements there is not always a sharing of electrons as contemplated in Sidgwick's theory. According to our point of view, a true co-ordination bond occurs when the spin moment of one of the uncoupled electrons in the third shell of the central atom is neutralised by the spin moment of one of the two electrons supplied by the co-ordination group. This leads either to a complete neutralisation of the magnetic moment of the central atom or to a large reduction in its value.

From this point of view it is interesting to compare the magnetic moments of $[Co(NH_3)_6]Cl_3$ and $[Co(NH_3)_6]Cl_2$ with that of the simple salt $CoCl_2$. The first one is diamagnetic, and in it the NH_3 groups are replaceable by Cl with a lowering of the valency of the radicle, while the second compound has a magnetic moment almost the same as that of the simple salt, namely, 25 Weiss's magnetons, while that calculated according to Sidgwick's theory is 8·6.

Thus we see that the first one is a true co-ordination compound and the second is an associated compound. According to the view proposed here, since a co-ordination bond is a weak valency bond between the central atom and one of the co-ordinated group, the presence of such a bond ought to manifest itself in the Raman spectra. We have photographed the spectra of the radiation scattered by solutions of these two hexammine compounds, and have found definite evidence of the presence of modified lines in the case of the cobaltic compound, but not in the case of the other (Fig. 1). The mercury lines used by us were:



Mercury arc. $[Co(NH_3)_6]Cl_2$. $[Co(NH_3)_6]Cl_3$.

FIG. 1.

	λ.	ν.	Intensity.
A	3650·2 A.	27,388 cm.$^{-1}$	10
B	3654·8	27,354	6
C	3663·2	27,291	10

In some cases, by using a filter of Wood's glass (transmission 390-320 mμ), we have cut off all the other strong lines of mercury except those given above. With the cobaltic solution we obtained the following modified lines:

	λ.	ν.	Δν.	Origin.	Δν.	Origin.
a	3715·8 A.	26,905 cm.$^{-1}$	483	*A* − *a*	575	*A* − *b*
b	3728·5	26,813	478	*c* − *b*	562	*C* − *c*
c	3740·2	26,729				

It is supposed that the modified lines are due to the two strong mercury lines denoted by *A* and *C*, and the middle one represents two lines not resolved. That the absence of modified lines in the radiation scattered by the cobaltous compound is not due to the difference in the absorbing powers of the two solutions in this region is supported by the fact that while $[Co(NH_3)_6]Cl_2$ has an absorption band only at 519 mμ, $[Co(NH_3)_6]Cl_3$ has two, one at 515 mμ and another at 349 mμ. Similar modified lines also appear with a solution of $[Co(NH_3)_5Cl]Cl_2$.

Melting Points of Nitrobenzene and of Benzene.

IN recent issues of NATURE, Messrs. Wolfke and Mazur have recorded discontinuities in the temperature coefficients of the density and of the dielectric constant of nitrobenzene; and they specify the melting point of their purified material as 5·5°.[1] It appears that this is taken by them to be the true melting point of nitrobenzene of really high purity.

Eight years ago, Roberts and Bury[2] reviewed the very various melting points—ranging from 3° to 9°—which are recorded for this substance; and by purifying commercial nitrobenzene they obtained constant fractions which melted 0·175° higher (by a Beckmann thermometer) than did purified dry benzene. Accordingly, accepting for the melting point of the latter compound the value 5·493° given by T. W. Richards, Carver, and Schumb,[3] they stated the melting point of nitrobenzene as 5·668° ± 0·010°. They also noted and measured the marked depression of melting point caused by traces of moisture, atmospheric or other. These figures, 5·493° for benzene and 5·67° for nitrobenzene, are quoted in the International Critical Tables as suitable datum-marks in precise thermometry.

It will be seen that the figure given by Roberts and Bury is nearly 0·2° above that of Mazur and Wolfke; this is not easy to explain, unless the latter's material were, after all, not as pure as the former authors', or unless the American figures for the melting point of benzene were too high.

Recently I needed some really pure nitrobenzene, and made it by the following method. Benzene, bought from Messrs. The British Drug Houses as "Extra pure, for molecular weight determination", and melting near 5·5°, was fractionally frozen between 5·58° and 5·38° in a slow current of pure dry hydrogen, in such a way that it took eleven hours to freeze out 210 gm.—two-thirds of the original—as a clear icy tube. This solid melted steadily at 5·58°, and the same figure was obtained a month later when phosphorus pentoxide was added to a 40 c.c. sample.

Of this purified benzene, 2 gram-molecules were mononitrated by hand for five hours at 45° (finally 60°) with a slight excess of a pure mixed acid of molar fractions H_2SO_4 (0·33), HNO_3 (0·18), H_2O (0·49), which acid I had found, in other work, not to dinitrate nitrobenzene. The product (98·5 per cent yield) was washed, dried, and distilled from phosphorus pentoxide below 64° (1·0–1·5 mm.) in an all-glass apparatus; the middle fraction was then put through exactly the same process of fractional freezing (5·80°–5·50°) as that described for the benzene. The solid fraction (four-fifths) melted at 5·84°, and this was repeated with a sample containing phosphorus pentoxide a month later. The liquid fraction, after being redistilled *in vacuo*, melted steadily at 5·83°. Exposure to air, or in rubber-stoppered vessels, lowered the melting point by about 0·1°. The thermometers were standardised by the National Physical Laboratory immediately after the end of these tests, and the temperatures given are true to the nearest 0·05°.

It thus appears that: (1) The melting point of benzene suggested by T. W. Richards as 5·493° is about 0·1° too low and should not be taken as a fixed point in precise thermometry. The value 5·58° agrees with the result obtained by Sydney Young. (2) The melting point of dry nitrobenzene is close to 5·85°. Judged by this, as also by the original standard of Roberts and Bury's materials, the melting point given by Mazur and Wolfke is decidedly low. I should not regard either my benzene or my nitrobenzene as being of the highest attainable purity; but the constancy of their arrest-temperatures for an hour or more, during the transition from liquid to solid block, indicates that the impurity, if any, was in each case extremely small.

Spectrum of Glow-worm.

It is well known that the luminous organs of insects like the fire-fly represent one of the most efficient sources of light, in that almost all the energy is concentrated in a narrow band in that part of the spectrum to which the human eye is most sensitive. In the case of the fire-fly, the spectrum photographed by Mr. Ives[1] shows that this band extends from 5230 to 6550 A.

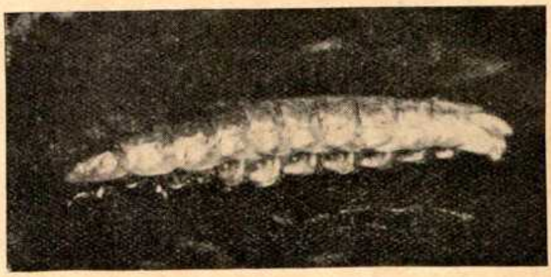

FIG. 1.

We had recently an opportunity of photographing the spectrum of a glow-worm which belongs probably to one of the species of Lampyridæ. Figs. 1 and 2 illustrate the worm in two positions and magnified about one and a half times. The portion indicated by an arrow in Fig. 2 shows one of the two luminous organs of the worm. The spectrum of the light emitted was photographed on an Ilford panchromatic plate with a night-sky spectrograph. An exposure of about fifteen minutes was found sufficient when a fairly narrow slit was used. The spectrum consisted of a single band extending from 5290 to 5860 A., that is, only half as broad as the

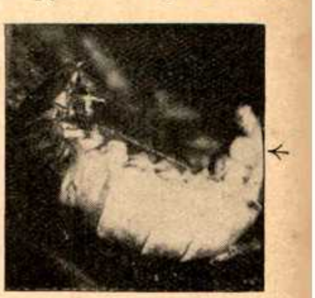

FIG. 2.

band in the spectrum of the fire-fly. Fig. 3 is an enlarged reproduction of the spectrum.

The glow-worm was not seen to emit any light by day even when observed in a dark room. Even at night the emission is not continuous. The worm can apparently do this at will. Slight irritation or shaking seems to make it well disposed to glow very brilliantly.

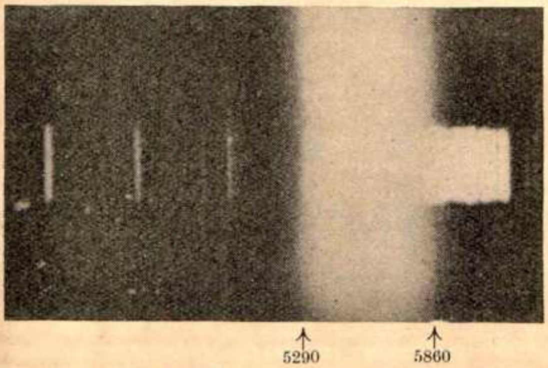

FIG. 3.—Spectrum of light from a glow-worm with a comparison spectrum (neon).

The Viscosity of Liquids.

IN NATURE for April 12, 1930, Prof. E. N. da C. Andrade states his theory of the viscosity of liquids as based upon "a temporary union of molecules in contiguous layers". This theory has been proposed in order to account for the temperature variation of the coefficient of viscosity in liquids, which is opposite in sign to that of gases. The nature of viscosity must be importantly different in a liquid and a gas.

It is the purpose of this brief letter to direct attention to the agreement of the theory of Prof. Andrade with the conception of the nature of the liquid state which arises from X-ray diffraction studies of various liquids. It is common for physicists to regard a liquid from the point of view of the nature of a gas, although in practically every kind of physical measurement except fluidity the liquid is more like the crystalline than the gaseous state, and even this exception is more apparent than real. The X-ray experiments have shown that there is coherent diffraction in liquids analogous to that in a crystal. Instead of sharply defined periodicities of structure in liquids there are found bands of periodicities. There is molecular arrangement caused by the molecular fields which cannot be accounted for by the existence of that portion of the field which has the effect of a shape or volume. This somewhat orderly arrangement of molecules is unstable; the distance of molecular separation is a matter of probability. At any instant there are spots throughout the liquid where the molecules have a more orderly arrangement which fades off into one of much less regularity. These spots or groups are not merely instantaneous, for periodicity occurs frequently in more than one direction—indeed, sometimes it is detectable in three, but there is also a constant change occurring in the constituents of a periodic region. This structure of a liquid is not crystalline. A word is needed, and I have suggested 'cybotaxis' as indicative of space arrangement.

Now the theory of Prof. Andrade postulates a duration of the 'temporary union' of molecules which does not exceed the very brief time for the molecules to acquire a common velocity of translation. Obviously the cybotactic condition is not described precisely in this manner, but the theory of Andrade may be said to represent one aspect, and may therefore be said to be to this extent in harmony with the cybotactic conception of liquid structure.

According to my own view, in these well-ordered spots or groups the slippage of one layer past the other is hindered by the molecular fields, and hence the larger or more perfect these groups the greater the viscosity of the liquid. This view is borne out by an examination of 22 octyl alcohols. Here a definite correlation has been found between the perfection of the orderly arrangement and the viscosity. The results are shortly to be published. It is clear that the effect of rising temperature would be to reduce the extent of a well-ordered group, and hence to decrease the viscosity.

It would seem therefore that X-ray diffraction experiments indicate strongly that Andrade's theory is in the correct direction, though not yet developed in accordance with my interpretation of the periodicities clearly evidenced by X-rays.

Nature of Viruses.

READING General Smuts's presidential address to the British Association and listening to a sectional discussion on the nature of viruses, I have been wondering whether the following will satisfy those who find great difficulty in believing that things so small as the agent of foot-and-mouth disease or the bacteriophage can be live organisms. General Smuts says that the world is constructed on a biological plan, that it is made up of events, and that matter, life, and mind are three grades of the same thing. In common thought, inorganic phenomena are quantitatively related to the matter with which they are associated. Mind, on the other hand, has no perceptible quantitative relations. Life would be generally considered to be quantitatively related either (by the mechanist) to living matter or (by the organicist) to living organisms. But need this always be so? Cannot life sometimes or partly be more like mind, so that the events of life are quantitatively out of proportion to the perceptible matter involved?

A. E. BOYCOTT.

Radlett, Oct. 4.

Spin of Light Quanta.

[BY RADIOGRAM.]

THE possession by photons of intrinsic angular momentum is further strikingly confirmed by investigations of light scattering in liquids. The spin theory indicates diminution of rotational scattering to half the value given by classical considerations. Spectroscopic measurements of the depolarisation of scattered light, using broad and fine slits, furnish a convenient test. Observations by Venkateswaran with carbon disulphide and benzene liquids quantitatively confirm the predicted results.

Research Items.

Were-Tigers in India.—In *Man* for October, Mr. L. A. Cammiade points out that in an article appearing recently in the *Illustrated London News*, and describing the killing of a man-eating tiger which had been responsible for the deaths of more than thirty people, there are indications that, all unknown to the hunter, Mr. L. Handley, the tiger he was hunting was, in the opinion of the jungle people, the Gonds, a man who by magical means had assumed that form for nefarious ends. Thus, although the Gonds are normally quite unafraid of tigers, they deserted Mr. Handley when he was approaching the place in the jungle where the body of a woman was being devoured. They would not follow the blood trail except in a crowd and with the beating of drums and letting off of fireworks. This would have frustrated his object had the tiger been an ordinary beast; but is intelligible as against witchcraft. In one case the body was placed in a tree after recovery; but this is a practice of the Koi and Konda Reddis, neighbouring jungle tribes, in similar cases. For some unknown reason the body must not rest on the ground. Mr. Handley would not be aware of the Gonds' belief, as to voice their suspicion above a whisper, even among themselves, might be followed by murder. Mr. Cammiade also points out that the deities "who have to be propitiated after the killing of the tiger", according to Mr. Handley's account, judging from their appearance, are not tiger deities but more probably the images of notable ancestors to whom an offering of thanksgiving was made for delivery from the were-tiger. Tiger deities would have to be propitiated, and consent obtained before any action was taken; while it is customary to ask the ancestors for protection on a journey through the jungle and for success in disposing of merchandise at its end.

Oceanic Bird Wanderers to Ceylon.—Under this title W. E. Wait describes twenty species of birds which appear casually in the neighbourhood of Ceylon (*Spolia Zeylanica*, vol. 16, p. 181, Aug. 1931). They comprise three species of terns, three frigate-birds, one booby, tropic bird, shearwater, and stormy-petrel, all of which may be said to frequent the tropical waters of the Indian Ocean; two gulls which are casual wanderers; and rare stragglers, including a shearwater and booby from the temperate South Indian Ocean, two skuas and a petrel from the Antarctic, and a petrel, a stormy-petrel, and probably a skua from the Northern Pacific Ocean. It seems likely that the location of Ceylon at the focus of many important steamer routes may have some bearing upon the appearance of these wandering birds, since it is known that many oceanic birds follow ships for long distances at sea.

A Supposed Primitive Gill-less Nudibranch.—A new family (Okadaiidæ) has been created by Kikutaro Baba for a gill-less holohepatic nudibranch, *Okadaia elegans*, described by him a year ago (*Annot. Zool. Japon.*, vol. 13, p. 63; 1931.) The new description deals in detail with the internal organisation of the sole species of the genus, which has been found at several localities on the Japanese coast. Until now, the only known gill-less dorid, of the tribe Holohepatica, has been *Doridoxa*, and while the main characters of *Okadaia* show that it belongs to the Holohepatica, there are others which recall in some degree the Cladohepatic series. The most striking structural characteristic described is the absence of a heart, for the sections revealed no trace of a proper pulsatory centre or the heart and pericardium comparable with those in other nudibranchs. Sir Charles Eliot was of opinion that the absence of gills had little effect on the rest of the organisation; this unique case of the correlated disappearance of branchiæ and the proper circulatory centre is regarded by the author as "the most primitive or retrogressive form" (surely not the same thing!) amongst the dorids.

Nature of Golgi Substance.—In Papers from the Tortugas Laboratory of the Carnegie Institution of Washington, vol. 27, is an interesting publication by D. H. Tennant, M. S. Gardiner, and D. E. Smith, on a cytological and biochemical study of the ovaries of the sea urchin, *Echinometra lucunter*. A new method is introduced into the study of cell inclusions by examining them both as structures and as substances. The tissues were subjected to the usual fixing and staining techniques, and at the same time the tissues were analysed and separated into their component substances. These substances were then subjected to the same fixation and staining techniques as the tissues themselves. As a result, the authors come to the conclusion that neither Golgi bodies nor chondriosomes are constant structural elements in the cellular architecture, but that both are the chemical products of physiological processes. It would seem that fatty acids of the oleic series meet the requirements of a Golgi substance in their reaction with osmium tetroxide. In the same report, observations are given on the formation of the egg in *Echinometra lucunter*, by R. A. Miller and H. B. Smith.

Rust Diseases of Cereal Crops.—A very useful summary of the present state of our knowledge of the commoner rust diseases of cereals is contained in the presidential address by Sir R. H. Biffen to the British Mycological Society (*Trans. Brit. Mycol. Soc.*, vol. 16, pt. 1, pp. 19-37). The strains and biologic forms of *Puccinia graminis* and other rusts are discussed in concise, though masterly fashion, and the recent work by Stakman and his colleagues on the crossing of forms is reviewed. Methods of control are dealt with at great length and include a historical as well as a modern presentation. Many factors which affect the incidence of epidemics are described, and the value of the removal of the ascidial hosts of such species as have them is discussed. The most valuable part, however, is the collection of recent results of work on the breeding of wheat resistant to the rust. The academic mycologist and the applied biologist will both find matter of interest in this account.

Geological Map of Finland.—Nearly twenty years have elapsed since the publication of the last edition of a general map of the ancient rocks of Finland. A new edition was prepared in 1925 for inclusion in the "Atlas of Finland", and this, with a few minor changes, is now published with *Bull.* 91 of the Commission géologique de Finlande. The Bulletin is a beautifully illustrated general account of the Pre-Quaternary rocks by Prof. J. J. Sederholm. The Pre-Cambrian rocks formerly known as Jatulian, Kalevian, and Ladogian are provisionally united under the common name *Karelian*. The levelled-down mountain chains which originated when these formations were folded are called *Karelides*. Their geotectonic study has already shown that they possess a structure analogous to that of the Alps. Mountain chains of a still more remote period are found from middle Sweden through southern Finland and these are designated *Sveco-Fennides*. It is shown that during the Pre-Cambrian, periods of erosion and quiet sedimentation were several times interrupted by epochs of orogenic folding and intrusion of granite, and it is thought probable that in these early ages, as since, mountain-building has been restricted to narrow belts of the earth's crust.

Absorption Spectra of Complex Salts.—A paper by Dr. R. Samuel in a recent issue of the *Zeitschrift fur Physik* (vol. 70, No. 1) contains much new information on the absorption spectra of complex salts of iron, cobalt, nickel, palladium, and platinum. The measurements have been made both in the visible region and well into the ultra-violet (2300 A.), the progress towards shorter wave-lengths being due to an improvement in technique, involving the use of the continuous spectrum of hydrogen as a light source. Graphs are given showing the variation of absorption coefficient with wave-length for twenty-one substances. The chief interest in these experiments is in their possible bearing on the structure of the complex radicles. Dr. Samuel records a number of apparent regularities, such as the existence of three similarly situated bands in the spectra of the diamagnetic cyanides and the appearance of a fourth band at greater wave-length with paramagnetic cyanides. His work, although extensive, is, however, definitely of a preliminary nature. The physics department of the Muslim University of Aligarh, of which Dr. Samuel is the head, is being reorganised and equipped to provide facilities for research in molecular physics, and he is continuing his work there.

Explosions in Closed Cylinders.—There is a pronounced increase in the speed of propagation of flame in a gas mixture in a tube open at both ends when a number of restricting brass rings are arranged within the tube. This effect, observed by Chapman and Wheeler in 1926, has been shown by Kirkby and Wheeler, in the *Journal of the Chemical Society* for September, to apply also to a closed tube. In explanation of the general effect of restrictions, it has been shown that during the early stages of an explosion in a tube the unburnt mixture ahead of the flame front moves as a current and the speed of the flame depends on the speed of the current. When the restricting rings are close enough together, the tongue of flame issuing from the first ring passes through the second and initiates combustion of the gas beyond while the portion between the two rings is still burning. The combustion of a comparatively large volume of gas is thus almost instantaneous. The effect occurs also in closed tubes, the sudden expansion resulting from the almost simultaneous combustion of the gas in each compartment producing a shock wave.

Rhenium Compounds.—The preparation of rhenium tetrachloride, and the rhenichlorides of potassium and silver, is described by Briscoe, Robinson, and Stoddart in the September number of the *Journal of the Chemical Society*. Precipitates of insoluble rhenichlorides were also obtained with mercurous and thallous salts. The primary product of treating the metal in chlorine is the tetrachloride, $ReCl_4$, which has not previously been observed. No evidence of the existence of the reported hexa- and hepta-chlorides was obtained, although the black crystalline tetrachloride was always accompanied by traces of a brown, well-crystallised substance, melting sharply at about 21°, obtained in quantities insufficient for analysis. No evidence of the formation of a lower chloride was obtained when rhenium was treated in dry hydrogen chloride up to 900°, the metal being unattacked. Potassium rhenichloride, K_2ReCl_6, was obtained in green crystals by heating a mixture of rhenium and potassium chloride in chlorine and crystallising from cold water. The silver salt, Ag_2ReCl_6, was obtained as an orange precipitate on adding a slight excess of silver nitrate to an aqueous solution of potassium rhenichloride. It is not obviously crystalline. Preliminary experiments on the behaviour of metallic rhenium when heated with bromine and iodine confirmed the observations of Noddack: the products are regarded as tetrahalides.

Astronomical Topics.

Meteoric Hypothesis for the Origin of the Solar System.—The Abbé Moreux contributes articles on cosmogony to *Scientia* for September and October. Instead of invoking the approach of another star to the sun, he supposes the sun to have traversed a region of space full of dust or meteoric matter, such as are indicated by the dark 'Horse's Head' in Orion and a number of similar dark patches. The orbits of such particles about the sun would in general be hyperbolic, but he suggests that by collisions and other mutual interference a considerable part of the matter might be captured by the sun. He traces its subsequent behaviour in some detail, and attempts an explanation of Bode's law of planetary distances. He notes that the planes of the giant planets are alternately on opposite sides of the invariable plane of the system; he draws an argument from this in support of his system. But the planes are in a state of constant change, and it would seem that proof is required that the relation now existing is permanent before any cosmogonic argument can be drawn from it. In his discussion of Neptune's system he assumes that Neptune's rotation is retrograde, like the motion of the satellite. The observations of J. H. Moore and D. H. Menzel at the Lick Observatory in 1928 showed that the rotation is direct. In such a difficult subject as cosmogony, it is well that all possible suggestions should be examined. It is unlikely that any one of the suggested systems is completely true.

Repetition of the Michelson-Morley Experiment.—Six years ago, Prof. D. C. Miller announced the results of a series of experiments that he made on Mt. Wilson; these seemed to indicate a variation of some 9 km./sec. in the course of the year, which he ascribed to a drift of the solar system in a direction nearly normal to the ecliptic. In the "Encyclopædia Britannica" (14th edition, vol. 15, p. 418) are described three series of experiments, by Kennedy and Illingworth, by Piccard and Stahel, and by Michelson, Pease, and Pearson, all made between 1927 and 1929, and all giving a zero effect like the original experiment.

The *Scientific American* for October gives details of a later series of experiments carried out by Prof. G. Joos, of the University of Jena, using apparatus constructed by the Zeiss works. The path of the light in the apparatus is brought up to 70 feet by repeated reflections. The results are recorded photographically and they are stated to preclude any ether drift exceeding one mile per second, so that it may be assumed to be zero. The large cross of the apparatus is constructed of quartz, for the double reason of its low coefficient of expansion and its freedom from magnetic effects. The cross is suspended by 700 springs of piano-wire, so as to support every part equally and prevent torsion. There is thus a great majority of experiments that indicate a zero effect of ether drift.

Africa in Transition.*

DURING the last fifty years, Africa has passed from the age of the pioneer and of geographical exploration, and has become a mosaic of more or less organised territories, controlled by European Powers. But although Africa has made such an advance that Nairobi, where forty years ago no vestige of human life was to be seen, is now a modern city with hotels and cinemas, in the less accessible parts, off the rail and main roads, tribes still exist as we knew them long ago: men and women nude, the only instrument of agriculture a pointed stick, and money in the form of coin still unknown. What has been the effect of the impact of the twentieth century on these relics of the stone age? This is the field of the new exploration of Africa, the field in which we need the assistance of the practical and constructive anthropologist.

As contact with modern civilisation must have a profoundly disruptive effect on the social organisation of a primitive society, and this effect is a continuing process, it is, therefore, essential for the anthropologist, administrator, and educator, in endeavouring to build foundations capable of bearing a permanent superstructure, to remember that they are dealing with a people in a period of social and intellectual transition. In other words, scientific research, in so far as it is concerned with practical work, must be directed to the African of the future rather than the African of the past or even as he is to-day, though an apprehension of both is essential for an understanding of the tendencies of the future.

Great changes have been brought about by the introduction of law and order and the suppression of slave-raiding. The concentration of the use of force into the hands of a central authority has *pro tanto* undermined the power and authority of the chief, and deprived the youth of Africa of its normal occupation of fighting and military service; while the suppression of war and slave-raiding has broken down the isolation of communities, so that the individual is able to offer his services as a wage labourer hundreds of miles away from his home. He has become acquainted with the conditions of life in an urban native quarter, and has acquired the command of money. This has also assisted in the spread of disease.

These are the inevitable effects of the white man's rule. When we come to the methods of applying that rule, there are two principles, generally known as assimilation and association.

The theory of assimilation would assign age-long tradition, customs, and beliefs to the scrap heap and substitute for them the modern forms of democracy, making the African a black European or black American. This system has been adopted by France in West Africa, but a growing body of opinion in France doubts the wisdom of this policy. An analogous system, though stopping short of miscegenation and conscription, known as 'direct rule', has been adopted widely in British dependencies. It is the system of which the results are now to be seen in India.

The alternative system of association works by devolution to native communities of the management of their own affairs, subject to the supreme authority of the governor and the law of the land. It recognises native institutions as the basis on which to build, and aims at their progressive improvement and adaptation to the changing conditions of Africa. Which of the two systems shall Africa in transition follow? The answer brooks no delay. Great Britain must choose between the two systems, and on that choice the future of Africa depends. One thing is certain, that with the spread of education the African will not remain inarticulate.

Contact with the white man brings the African face to face at once with the fundamental conflict of conceptions between the communal outlook, upon which his life and actions have been framed, and the individualism taught by his dealing with the white man. His employer tells him his wages depend upon his individual exertions; the missionary tells him to obey the laws of God if he would save his own soul, and that tribal expiation will avail him nothing. These are new conceptions; for his dominant characteristics are identification with his clan and belief in the presence and potency of the ancestral spirits of the tribe. Missionaries of long African experience believe that it is possible to engraft pagan rites on Christianity as they were in the early Church, while the Standing Advisory Committee of the Colonial Office has declared that what is good in the old sanctions and beliefs should be strengthened and retained. It is a problem that cannot be ignored. The new policy, too, in secular education will have a profound effect on the future of Africa.

The economic development of the resources of Africa is having an effect on African life, which is receiving intensive study by the International Institute of African Languages and Cultures. The access of wealth which has followed the opening up of Africa by road and rail, making possible the export of additional material produced by the extension and improvement of methods in agriculture, has greatly raised the standard of life.

It lies with us to see that the conclusions of science are rightly applied, and that the transition of the African from a lower to a higher standard of life and civilisation may be guided by a well-considered policy and scientific study, not only of the African as he used to be, but as he is to-day, and more especially of the tendencies which will operate to change him still more to-morrow.

---

* Substance of a lecture by Lord Lugard, delivered on Sept. 24 at a joint meeting of Sections E (Geography) and H (Anthropology) of the British Association.

Control of Finance.

AT the recent meeting of the British Association, Mr. P. Barratt Whale read a paper to Section F (Economic Science and Statistics) on the Macmillan Committee's Report on Finance and Industry. This Report, he said, is as important to-day as when first printed, despite the crisis that has since occurred. The country no doubt will come through this crisis, and once more it will be necessary to operate the gold standard system, though it is desirable that this should be done on lines more satisfactory than in the immediate past. In the future, therefore, the Macmillan Report will be looked to for guidance.

The keynote of that Report is that currencies should be managed from the point of view of stabilisation of prices, and this is in accordance with the general trend of modern ideas in monetary science. It is, however, in marked contrast with the views which prevailed during the nineteenth century, when it was generally held that the gold value of the currency should remain unchanged. Now the main aim is to secure that the currency represents a definite standard of value in terms of its purchasing power, so that the price level can be stabilised. Stabilisation, however, may mean one of two things, and it will therefore be necessary to decide on the particular kind of stabilisation which is most desirable. Either the level of commodity prices as measured by the wholesale index number can be stabilised, or allowances can be made for changes in productive conditions which may imply variations in general prices not needed to be corrected by a process of stabilisation.

The first type of arrangement aims at complete stability in commodity prices, while the second would allow some variation in prices, so far as that variation should be attributed to general changes in productive conditions. Mr. Whale considers that the Macmillan Committee was justified in shirking a choice between these two methods, but a choice will have to be made and it is important for economists to determine what kind of stabilisation is most desirable. Currency systems will require to be managed by the central banks with much greater freedom than hitherto.

Restrictions which have existed in the past have proved harmful, since they have generally operated to lock up gold. It is not enough for the central banks to control the domestic situation only, as against the influences of the other banks in the country ; the gold standard also implies that the currencies of the different countries should move together and have a closely related balance. There should thus be common aims and a common policy for all the central banks of the world. The Report took the view that the existing unequal distribution of the world's gold supply is not a cause but rather the result of causes—namely, the definite intention of France and the United States to accumulate gold. But there is another view which the Committee did not put forward, and that is that the accumulations of gold might not have been deliberately acquired by these countries but might have flowed as a result of the balance of international payments.

On this view the fundamental cause was the unbalanced state of indebtedness. The remedy, if this be the cause, is that France and the United States should either lend more abroad or should import more goods. Mr. Whale considers that the Committee has failed to give sufficient emphasis to the importance of price adjustments in balancing indebtedness. Both France and the United States have refused to allow a rise in their internal price levels, but if this had been permitted it would have facilitated imports into these countries from the rest of the world.

The Macmillan Report represents a combination of the ideas of the currency school with those of the banking school. The latter insists on the need for elasticity in currency arrangements, while the former emphasises the necessity of strict regulation of currency. Control, however, should be exercised by the central banks, so as to secure stability in the price level. The Report is on the right lines, but it is clear that in many respects the ideas of the Committee require to be worked out in detail, and some of its fundamental assumptions might be challenged.

The Unit of Atomic Weight.

DISCUSSING the unit of atomic weight before Section A (Physics) at the meeting of the British Association in London on Sept. 28, Dr. F. W. Aston contrasted the point of view of the physicist and the chemist. The painstaking research in recent years to determine whether the atomic weights of complex elements vary with their origin and to effect the separation of isotopes has proved conclusively that for practical purposes variation in Nature is negligible, and has justified the decision of the Committee of the International Union of Chemistry to retain the old relative meaning of the words ‘element’ and ‘atomic weight’. There is little reason to alter the present unit of atomic weight, $O=16$, which has figured so long in chemical literature.

The physicist, on the other hand, is interested in the actual weights of the atoms, and it is only in the last twenty years that any comparison of the actual weights of the individual atoms has been possible. The original parabola method of Sir J. J. Thomson was followed by the first mass-spectrograph, in 1919, with a resolving power of 1 in 130 and an accuracy of about 0·1 per cent. With few exceptions, atomic weights deduced from mass-spectra agreed well with those generally accepted. The second mass-spectrograph, built in 1925, with a resolving power of 1 in 500 and an accuracy attaining 0·01 per cent, permitted the calculation of the percentage deviation of weight of an atom from a whole number on the scale of $O^{16}=16$. During the last three years a valuable check on chemical calculations has been provided in a photometric method of calculating the relative abundance of isotopes from the intensity of their lines on mass spectra, which has been used to determine the mean atomic weights of complex elements.

After discussing Giauque and Johnston's announcement that observations on oxygen band spectra indicate the presence of O^{17} and O^{18}, requiring alternatives to oxygen as our standard, Dr. Aston stated that he is in favour of retaining the present chemical scale unaltered. For most practical operations the chemist only requires a list of numbers, accepted internationally and guaranteed to within 0·1 per cent of the true atomic weights. For the fundamental requirements of physics the neutral atom of oxygen 16 appears to be the best standard, being the most convenient for work with band spectra and mass spectra. The 0·01 to 0·02 per cent difference in the two scales is not serious, and the meaning underlying the chemical scale differs so completely from that underlying the physical that confusion can easily be avoided by speaking of ‘the atomic weight of chlorine’ on one hand and ‘the weight of the atom of chlorine 35’ on the other.

The Greenland Cod.

IN the recently published report of the North-western Area Committee of the International Council for the Exploration of the Sea,[1] much interesting and valuable information is brought together on the natural history and biology of the Greenland cod (*Gadus callarias*). This fish appears every year in Greenland waters, but its numbers are subject to most violent and sudden fluctuations.

About the year 1820, the date of the earliest available records, cod were present in enormous numbers in the Julianehaab district, and even so far north as Disco Bay. Thereafter they disappeared from all but certain fiords and sounds in the vicinity of Sarfânguak and Fiskenaesset in the south-west for roughly a quarter of a century. During the period 1845–49 they were back again in large numbers, but by the end of 1850 scarcely a fish remained. During the second half of the nineteenth century and the first two decades of the present century, cod continued to be scarce in Greenland waters. More recently, however, they have once more reappeared in enormous numbers, and in the year 1929 were again numerous so far north as Disco Bay.

Besides this recent enormous increase in the stock of cod, other changes also have taken place. Previously, in their lean years, the cod approached the coast only in the summer and autumn months, whereas now they come inshore and enter the fiords as early as March or April.

This great change in habit and increase in the stock of cod in recent years is not the only indication of fundamental changes in the animal life of the waters of south-west Greenland. Shoals of coalfish (*Gadus virens*) have also frequently been seen with the cod in various districts since 1924. The herring, too, a fish practically unknown around Greenland in normal times, has recently appeared in large numbers; and even haddock, not previously recorded from its waters, have been taken.

The climate and other natural conditions at south-west Greenland have also been quite out of the ordinary. The winters have been unusually mild, and the western ice has had a much more restricted distribution than formerly. The causes underlying the changes in the animal life of the area must probably be sought in the abnormal conditions in their environment, but sufficient data are not yet available for linking up cause and effect. There is of course every reason to expect a swing-back to normal conditions at any time; but if this reversion does not take place too rapidly, there is every prospect of a good cod fishery continuing off south-west Greenland at any rate until 1936. G. A. S.

The Fortin Barometer.

WHILE a barometer of the Fortin pattern is generally regarded as a better laboratory instrument than one of the Kew pattern, many observers prefer the latter, owing to the difficulty found in setting the mercury accurately to the pointer in the cistern of the Fortin barometer. If the illumination is good and the mercury clean, this setting provides no difficulty; but barometers are often of necessity set up in positions of poor illumination and the mercury surface becomes dull after a few years of use, so that accurate setting of the mercury to the pointer is rendered difficult.

Messrs. C. F. Casella and Co., Ltd., of Regent House, Fitzroy Square, London, W.1, have recently brought out a new pattern of Fortin barometer designed to overcome these difficulties. The object aimed at appears to have been achieved in a most satisfactory manner. The usual glass cistern is replaced by a cast-iron one, having a horizontal extension at one side, in which a stainless steel pointer is rigidly fixed. In the front of the extension is a small telescope directed down at an angle towards the pointer, and on the back a plane glass window. Behind the window a white illuminated surface is provided. With clean mercury the view through the telescope shows a clear-cut impression, on a magnified scale, of the pointer facing its image, and the two can be brought into contact by using the adjusting screw, which raises the level of the mercury in the cistern of the barometer, with great confidence and precision. In order that the mercury surface may not become contaminated, all air entering or leaving the cistern has to pass through a small filter, which is said to be effective even in the atmosphere of a chemical laboratory. This does not end the novel features of the instrument, as the horizontal chamber terminates in a glass window held in position by a screwed ring. If the mercury surface is lowered and this ring with the window removed, the inside of the cistern can be cleaned and, if desired, the mercury pumped out of the cistern and fresh mercury inserted.

Owing to the pointer being at some distance from the vertical axis of the barometer, it is of special importance that the instrument should be set up truly vertical. The makers point out that verticality is easily ensured by rotating the barometer in its mounting and noting that the pointer remains in contact with the mercury surface in all positions. The design undoubtedly marks an important step forward in the construction of Fortin barometers.

University and Educational Intelligence.

CAMBRIDGE.—The following have been elected to fellowships at Trinity College: Prof. G. H. Hardy, Sadleirian professor of pure mathematics in the University (professorial fellowship); Mr. L. C. Young; and Mr. H. S. M. Coxeter.

Mr. A. H. Chapman (St. Catharine's) has been appointed official secretary to the Department of Engineering.

The Regent House has passed a grace to the effect that the title of Professor Emeritus be conferred on Sir R. H. Biffen upon his retirement from the professorship of agricultural botany.

The electors to the Frank Smart studentship in botany give notice that the studentship is now vacant. Any graduate of the University is eligible, provided that not more than fourteen complete terms have elapsed after his first term of residence. Women are also eligible. The successful candidate must devote himself to research in botany under the direction of the professor of botany. The value of the studentship is £200 per annum. Applications must reach Prof. A. C. Seward, at the Botany School, on or before Oct. 24.

FOR the forthcoming general parliamentary election, the Universities of Cambridge, Oxford, and Belfast, and the Scottish Universities, are returning unopposed members, as follows: Cambridge, Sir John Withers and Mr. G. H. A. Wilson; Oxford, the Right Hon. Lord Hugh Cecil and Sir Charles Oman; Belfast, Col. T. Sinclair; Scottish Universities, Mr. John Buchan, Dr. D. M. Cowan, and Mr. A. Noel Skelton. On the other hand, the Universities of London and Wales and the Combined English Universities are to have a poll. The following are the candidates for election: London (1 member), Sir E. Graham-Little and Major A. G. Church; Wales (1 member), Mr. E. Evans and Mr. S. Lewis; Combined English Universities (2 members), Miss E. Rathbone, Sir R. Craddock, Mr. H. G. Williams, Sir William Jowitt, and Mr. H. Nicolson.

FROM the United States Office of Education we have received two bulletins of more than ordinary interest. The first, "National Ministries of Education" (pp. 158, price 25 cents), is a description, supported by statistical tables and a bibliography, of the status, functions, and activities of the ministries of education in fifty-five of the seventy-three main political divisions of the world: the remaining eighteen, including Germany, the U.S.S.R., the United States, India, Brazil, Australia, and Canada, are excluded because their ministries of education, where they have any, are less than national in their legal and functional characteristics. Under the heading " General Characteristics " are dissertations on the internal organisation of the ministry in Italy, Belgium, Persia, and Uruguay, and organisations advisory to the ministry in Hungary, Belgium, Spain, England, New Zealand, and Bulgaria. In a chapter on the relations of the ministry to secondary education, the systems in force in Spain, Portugal, and Rumania are described as typical of the twenty-five Latin language countries studied, those of Yugoslavia, Denmark, and Hungary for the Germanic type, and those of the Irish Free State, New Zealand, and England and Wales for the English language countries. Special chapters are devoted to the Board of Education of England and Wales and the ministries of France, Belgium, and Mexico. The other bulletin, on " Accredited Higher Institutions ", is a compilation of the lists of institutions of college grade accredited or approved or classified by recognised State or voluntary agencies, including national professional organisations, with descriptions of standard criteria used.

Birthdays and Research Centres.

Oct. 26, 1874.—Prof. T. M. Lowry, C.B.E., F.R.S., professor of physical chemistry in the University of Cambridge.

I am interested in problems of valency, especially in the compounds of nitrogen, phosphorus, sulphur, and tellurium, and in the study of molecular structure by physical methods. Optical and spectroscopic methods have been used extensively for this purpose; but researches on photochemistry, the diffraction of electrons, the scattering of molecular rays, electrode potentials, electrolytic conductivity, and lubrication are also in progress in the Laboratory of Physical Chemistry at Cambridge. In polarimetry, the study of optical rotatory power has been extended to vapours, and measurements are now being made of the form of the dispersion curves in the region of absorption within which the Cotton phenomenon is observed.

Oct. 27, 1856.—Prof. E. W. Hobson, F.R.S., formerly Sadleirian professor of pure mathematics in the University of Cambridge.

It is very improbable that, at my age, I shall be able to take up investigation of any new subject. I hope, however, to be able to fill up some gaps in subjects such as the theory of integral equations, and possibly in the calculus of variations; subjects at which I have worked in past years.

Oct. 27, 1894.—Prof. Lennard-Jones, Melville Wills professor of theoretical physics in the University of Bristol.

The theoretical researches in the Wills Physical Laboratory, Bristol, centre round problems of cohesion and molecular structure. The main investigations, in which we are now engaged, aim at (1) a detailed knowledge of the electronic structure of certain atoms and molecules, (2) a calculation of the cohesive forces between atoms in a molecule, (3) a correlation of certain properties of gases and solids with the electronic structure of the atoms and molecules of which they are composed.

Societies and Academies.

London.

Society of Public Analysts, Oct. 7—**J. Cecil Maby**: The identification of wood and wood charcoal fragments. The economic and forensic importance of distinguishing between different woods by their microscopical structure is discussed, and the value of the method in archæological investigations is illustrated by various examples, such as the identification of the nature of the wood in the piles of lake dwellings, and of the charcoal from ancient furnaces.—**T. Callan** and **N. Strafford**: The examination of dyed leathers in cases of alleged dermatitis. The possibility of applying to dyed leather the tests used by Cox for the detection of diamines and allied bodies in fur has been investigated. The tannins in leather may interfere with many of these tests, but four of them will enable definite conclusions to be drawn, provided that control tests are applied to portions of the extract from the leather, after the addition of very small amounts of a meta- and para-diamine respectively.—**W. L. Davies**: The determination of chlorides in dairy products and biological material. The advantages of a wet (nitric acid) method are described, and suggestions for obtaining a sharper end-point in the titration of the excess of silver nitrate are made.

Physical Society, Oct. 16.—**G. A. Wedgwood**: Young's modulus for steel in two directions in a bar. Experiments showed that the elastic constant E of the various steels from which the hollow cylinders used were made is the same in two directions at right angles, one direction being along the axis of the original bar and the other across a diameter.—**N. W. McLachlan**: On the effective mass of flexible discs and conical diaphragms used for sound reproduction. The effective mass of a circular aluminum disc vibrating in air is zero at the centre-stationary and centre-moving modes. At a centre-stationary mode the effective mass attains a positive maximum before the zero value and a negative maximum thereafter. From the shape of the curves for a disc it is possible to interpret those obtained for conical diaphragms. In the latter case the curves depend upon the apical angle of the cone.—**A. T. McKay**: Further study of diffusion for the infinite plane sheet. A method is developed whereby the diffusivity and surface constants can be evaluated from experimental data. In order to facilitate the practical application of the methods propounded to this and similar diffusion problems, tables have been specially calculated giving the first four roots of each of the four equations $\left.\begin{matrix}\tan\\ \cot\end{matrix}\right\}x = \pm x\,.\left.\begin{matrix}\tan\\ \cot\end{matrix}\right\}\lambda$.

Paris.

Academy of Sciences, Sept. 7.—**André Blondel**: New graphical solutions of calculations for electric cables transmitting at high voltage.—**E. Bataillon** and **Tchou Su**: The three types of mitosis characteristic of the first development in the egg of *Bombyx*, fertilised or parthenogenetic.—**R. Tremblot**: The application of (optical) interference to some problems of flow at high velocities. By means of the apparatus described in an earlier communication the author has measured the distribution of the densities in a Laval tuyère in order to decide between the conclusions of Prandtl, Steichen, and Stodola (rigorously adiabatic flow) and those of Müller (at constant heat). The curves obtained agree with the first hypothesis within one per cent.—**Jean Peltier**: The search for want of symmetry and faults in ferromagnetic test pieces. In the differential arrangement described and figured, any want of homogeneity in the test pieces is shown by the production of a note in a loud speaker.—**Maurice Billy** and **Félix Trombe**: The preparation of pure cerium. In various experiments the crucible holding the fused salt was carbon, porcelain, fused quartz, and fluorspar porcelain (Damiens). The best results were obtained with an apparatus consisting of a carbon crucible as anode, at the bottom of which was a quartz or fluorspar crucible. The cathode was a molybdenum cylinder. The metal contained 0·08 per cent of silicon, and no other impurity could be detected.—**P. Fallot**: The palæozoic massif of Talambot (Spanish Riff).—**Michel Polonovski** and **René Hazard**: Some physiological effects of chlorotropane. The esterification of tropanol by hydrochloric acid increases the toxic power of this alcohol: it reinforces the paralysing action of the latter on the cardiac vagus, and gives to the action of the molecule on the intestine a resemblance to that produced by nicotine.—**P. Cappe de Baillon**: The experimental bipartition of the odd pieces of the exoskeleton in *Tenebrio molitor*.—**René Wurmser** and **Louis Rapkine**: A method of quantitative micro-injection.

Geneva.

Society of Physics and Natural History, June 18.—**Paul Rossier**: (1) An astrophysical formula. A classical relation between the absolute magnitude, the radius, and the temperature of a star necessitates a term based on a simplifying hypothesis concerning the spectral sensibility of the eye. Replacing this by a much more probable supposition, the author gives this term a closer approximation.—(2) The calculation of the apparent diameter of a star. The author replaces an old relation between the apparent magnitude, the apparent diameter, and the temperature of a star, an equation holding for an integral receptor only, by a new formula including the magnitude furnished by any receiver whatever. Although the numerical constants are furnished by the sun, the application to giant stars, the diameters of which have been measured with the interferometer, gives results agreeing with observation.—**W. H. Schopfer**: The study of the influence of yeast extracts and concentrates of B vitamins on the sexuality of a fungus. Concentrated extracts of yeast were added to a rigorously synthetic fungal medium. A clear action has been observed on the development and on the sexuality of the fungus utilised.—**A. Amstutz**: The petrographic character of Banks Island in Melanesia. The author has defined the petrographic character of Banks Islands, which form one of the numerous archipelagos scattered in the Pacific and are attached politically to the Franco-English condominium of the New Hebrides. These islands are essentially volcanic in origin and are constituted of augite labradorites.—**E. Joukowsky**: A levigator with a motionless liquid medium. The author describes an apparatus designed for the study of fine sediments. This allows the classification of the sediments into a considerable number of grades, according to the differences in the velocity of fall in water. The ultra-fine elements which remain in suspension are obtained without loss.—**A. Schidlof**: The application of wave mechanics to nuclear physics. With reference to a recent work of M. Terroux on the energy of the β-rays emitted by radium E, the author remarks that, contrary to the conclusions drawn by M. Terroux, the results of his experiments furnish a striking confirmation of the quantum theory of radioactivity.—**Georges Tiercy**: The systematic use of the rotation of the transit instrument. The idea of turning the transit instrument for all stars has been sometimes attributed to the German astronomer Schnauder (1891). The author shows that Plantamour, director of the Geneva Observatory, had applied this idea so far back as 1868; the credit of using this innovation systematically in the simplest possible manner appears to belong to the Padua Observatory (1878). Hence Schnauder was anticipated.

July 2.—**A. Borloz**: Liquation phenomena in a coinage bronze. The author has taken several samples from different points of an ingot of coinage bronze. The analyses show nearly perfect homogeneity, except for the upper portion, the jet, where there is some liquation, as shown by a concentration in the copper and a reduction in the proportion of tin.—**A. L. Perier**: Contribution to the study of the maxillofacial correlations. Is the alveolo-palatal sagittal development related to the upper facial height? Observations on two cranial series, Bushmen and Alpine, give a negative answer. In fact, the alveolo-palatal region is modelled by the dental arch, the potential of growth of which is quite independent of the other facial diameters.—**E. Galopin**: The use of the polarising microscope in the determination of organic substances. Organic substances generally, possessing very high double refraction, can only be studied optically in very minute crystals of the order of 0·01 mm. The author has recognised that special operations are necessary for the production of such crystals; he (with Marc Cramer) has studied the special media for microscopical preparation. The measurement of the double refraction is made by a Berek compensator with convergent light on plates fixed parallel to the principal sections of the mineral studied.—**J. J. Pittard**: The bitumen of the Urgonian limestone and the molasse of Pyrimont (Ain). The author shows by numerous analyses that the proportion of volatile products of the bitumen is much higher in the Urgonian limestone (69 per cent) than in the molassic grits superposed (55 per cent). This suggests impregnation *per ascensum*, the hydrocarbons coming from deep layers and showing increasing oxidation towards the top.

Rome.

Royal National Academy of the Lincei, April 12.—**A. Lo Surdo**: Thermionic valves with fall of potential across the grid. A thermionic valve is described in which the grid consists of a conductor of suitable form for passing a current through it. By adjusting the intensity and sense of this current the non-uniformity of behaviour of the various parts of the filament grid space may be diminished or enhanced. In this way it seems possible to increase markedly the amplifying power of thermionic valves.—**Q. Majorana**: Certain new facts ascertainable by means of ordinary photoelectric cells. Further observations on the negative electrification of the photoelectric metal of an ordinary photoelectric cell when red light impinges thereon are described.—**M. La Rosa**: New proof of the influence of motion of the source on the velocity of light; ballistic explanation of Miss Leavitt's law (2).—**A. Del Chiaro**: Homogeneous functions.—**F. Tricomi**: Further observations on the distribution of the baricentres of the plane sections of a body.—**G. Palozzi**: A characteristic property of Darboux's tangents.—**Giacinta Andruetto**: The intrinsic equations of elastic equilibrium. Using the methods of absolute differential calculus, Tonolo has established the intrinsic equations of anisotropic or isotropic elastic bodies, including the case when the elastic body is immersed in a space of constant curvature. All these equations may be derived by rapid calculations by applying modern vectorial methods to the known vectorial equations for the equilibrium of elastic media.—**R. Calapso**: Surfaces of the third degree (of Cayley's type) united to the point of a given surface.—**R. Caccioppoli**: The united elements of functional transformations: an observation on the problems of limiting values.—**R. Serini**: The integrals of the equations of propagation in one dimension.—**G. M. Pugno**: Contribution to the treatment of doubly hyperstatic elastic systems.—**B. Novàkovà**: Microphotometric measurements of the line H_α at the centre and at the edge of the sun.—**R. Zoja**: The distribution of the tensions in a solid with rectilinear axis and with rectangular transverse section of variable height.—**C. Antoniani**: The behaviour in an electric field of colloidal humic-mineral complexes. A colloidal complex, extracted from soil by means of 10 per cent sodium hydroxide solution and afterwards purified to remove clayey constituents, and containing 82·75 per cent of organic matter and small proportions of inorganic matter, was found to be electronegative and to have its isoelectric point at *p*H 7·4. When the complex was flocculated at the isoelectric point and brought back to the disperse state by addition of sodium hydroxide, it exhibited anodic migration under the influence of an electric field. As the concentration of the hydroxyl ions is increased, the velocity of this migration increases to a maximum and then gradually decreases to zero, cathodic migration ultimately ensuing.—**G. Roberti**: Hydrogenation of the nitrogen compounds contained in primary tar. At 350° C., under a pressure of 100 atmospheres, and in presence of cobalt sulphide as catalyst, the bases of primary tar give rise to hydrocarbons, the nitrogen being liberated as ammonia. Aniline yields cyclohexane, cyclohexene, and small amounts of hydrogenated diphenyls. Pyridine gives pentane, amylene, hexane, hexene, heptane, etc., whilst quinoline is converted into propylcyclohexane, propylcyclohexene, and other hydrocarbons.—**M. Airoldi**: Fossil Corallinaceæ from the Canaries (2). *Porolithon inaspectum* n. sp. and other forms are described.—**G. Cannicci**: Bacterial flora of certain fish. Bacteriological examination of cod, pilchards, and mullet caught in the Gulf of Naples shows that the cœlom contains only bacteria; the gills contain mostly motile bacteria, with moulds and chromogenic micro-organisms in some cases. The pilchard is the richest in *B. proteus* and the cod in fusiform bacteria which liquefy gelatine. *B. vulgare* Hauser, which is able to degrade proteins with formation of toxic products, occurs most abundantly in the gills during the summer, and *B. proteus* is found only in small number during the autumn and winter.—**Amelia Tonon**: Structure of mulberry buds and their development (2).—**R. Perotti**: The struggle of cereals against *stretta*. Incorporation of finely divided wood or bone charcoal with the layer of soil pervaded by the root systems of chlorophytes of various families, including the Gramìnaceæ, results in diminished dispersion of water from the soil, the food reserves of which are utilised more efficiently.

Official Publications Received.

British.

Proceedings of the Royal Society of Edinburgh, Session 1930–1931. Vol. 51, Part 2, No. 17: The Ionizing Efficiency of Electronic Impacts in Air. By Dr. John Thomson. Diary of Societies.

FRIDAY, October 23.

Royal Society of Medicine (Disease in Children Section), at 5.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Specimens illustrating the Nature and Extent of the Changes which have Affected the Jaws of English People in Recent Centuries.

Society of Chemical Industry (Liverpool Section) (at Liverpool University), at 6—Dr. W. Trantom: The Barium Industry.

Institution of Mechanical Engineers, at 6.—Lt.-Col. E. Kitson Clark: Presidential Address.

Society of Chemical Industry (Newcastle-upon-Tyne Section) (at Armstrong College, Newcastle-upon-Tyne), at 7.30.—Dr J. T. Dunn: Chairman's Inaugural Address.

Junior Institution of Engineers, at 7.30.—I. Fagelston: Some Instruments used in connexion with Power Plant.

Royal Society of Medicine (Epidemiology and State Medicine Section), at 8.—Prof. Major Greenwood: The General Register Office (Presidential Address).

Royal Aeronautical Society (at Merchant Taylors' School).—C. R. Fairey: Lecture.

MONDAY, October 26.

Royal Society of Edinburgh, at 4.30.—Statutory Meeting.

Royal College of Surgeons of England, at 5.—C. P. G. Wakeley: Demonstration of Specimens of Primary Bone Tumours.

Institution of Mechanical Engineers (Graduates' Section, London), at 6.45.—W. W. S. Robertson: The Manufacture of Wire.

Institution of Electrical Engineers (Informal Meeting), at 7.—Discussion: Is the Engineer given his Due Share in Management?

Institution of Electrical Engineers (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—A. G. Shearer: Chairman's Address.

Institution of Automobile Engineers (Glasgow Centre) (at 39 Elmbank Crescent, Glasgow), at 7.30.—W. A. Tookey: The Internal Combustion Engine and its Performances (Presidential Address).

Society of Chemical Industry (Edinburgh and East of Scotland Section) (jointly with Institute of Chemistry—Edinburgh and East of Scotland Section) (at North British Station Hotel, Edinburgh), at 7.30—W. R. Guy: Housing the Industrial Chemist.

Royal Society of Medicine (Odontology Section), at 8.—E. B. Dowsett: Operative Procedure for Cysts of the Jaws.—J. G. Turner: (*a*) Backward Movement of Lower First Molars; (*b*) Difficulties of Extracting Retained and Unerupted Teeth.

TUESDAY, October 27.

Electrical Association for Women (at Lighting Service Bureau, 15 Savoy Street), at 3.—Mrs. Pender Chalmers: By Air to Baghdad, Babylon, and Ur (Lecture).

London Natural History Society (at London School of Hygiene and Tropical Medicine) (Annual General Meetings of Sections).—Archæology, at 6; Botany, at 6.30; Entomology, at 7; Plant Galls, at 7 30; Ramblers, at 7 45; Ornithology, at 8.15.

Institution of Electrical Engineers (East Midland Sub-Centre) (at College of Technology, Leicester), at 6 45.—Dr. A. B. Everest: The Use of Nickel in the Electrical Industry.

Institution of Electrical Engineers (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—R. G. Ward: Chairman's Address.

Royal Photographic Society, at 7.—Dr. E. Goldberg: Photoelectric Cells (Traill-Taylor Memorial Lecture).

Quekett Microscopical Club, at 7.—Gossip Meeting.

Institution of Automobile Engineers (Leeds Centre) (at Hotel Metropole, Leeds), at 7.15.—W. A Tookey: The Internal Combustion Engine and its Performances (Presidential Address).

WEDNESDAY, October 28.

British Astronomical Association (at Sion College), at 5.

North-East Coast Institution of Engineers and Shipbuilders (Graduate Section) (at Bolbec Hall, Newcastle-upon-Tyne), at 7.15.—L. O. Burrill and E. W. Fraser-Smith: Addresses.

Institution of Automobile Engineers (Manchester Centre) (at Engineers' Club, Manchester), at 7.30.—W. A. Tookey: The Internal Combustion Engine and its Performances (Presidential Address).

British Psychological Society (Medical and Industrial Sections) (at Medical Society of London), at 8 30.—Papers on Accidents by Prof. Major Greenwood, Eric Farmer, and Dr. G. Groddeck.

Institution of Chemical Engineers (Graduates' and Students' Section).—C. A. R. Stead: Crushing and Grinding with special reference to Ball Mills.

THURSDAY, October 29.

Royal Aeronautical Society (at Royal Society of Arts), at 6.30.—Capt. A. G. Lamplugh: Accidents in Civil Aviation.

British Association of Chemists (Notts and Derby Section) (at Technical College, Derby), at 7.—F. Scholefield: Vat Dyestuffs—their Application and Properties.

North-East Coast Institution of Engineers and Shipbuilders (Tees-Side Branch—Graduate Section) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—F. S. Fletcher: Chairman's Address.

Institution of Electrical Engineers (Irish Centre—Dublin) (at Trinity College, Dublin), at 7.45.—Lt.-Col. H. E. O'Brien: Chairman's Address.

FRIDAY, October 30.

Royal Astronomical Society (Geophysical Discussion), at 4.30.—Isostasy. Speakers: Sir G. P. Lenox-Conyngham (who will communicate a paper by Dr. De Graaf Hunter), Prof. A. M. Davies, Dr. Harold Jeffreys, H L P. Jolly, Prof. O. T. Jones. Chairman: Admiral H. P. Douglas.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Specimens illustrating the Anatomy of the Pyloric Sphincter in Cases of Hypertrophic Enlargement.

North-East Coast Institution of Engineers and Shipbuilders (in Mining Institute, Newcastle-upon-Type), at 6.—Mrs. E. M. Smith-Keary: The Effect of Immersion on Propellers.

Institution of Electrical Engineers (London Students' Section), at 6.15.—G. J. Shaw and G. A. M. Hyde: The Business of Electrical Apparatus Manufacture.

Institution of Chemical Engineers (at Institution of Civil Engineers), at 6 30.—Dr. E. F. Armstrong: Hydrogenation (Lecture)

Illuminating Engineering Society (at Royal Society of Arts), at 6.30.—P. Good and others: Discussion on Some Impressions of the I.I.C. Floodlighting.

Institution of Mechanical Engineers (East Midland Branch) (at University College, Nottingham), at 6.30.—Prof. C. H. Bulleid: The Importance of Metallurgy to the Engineer.

Institution of Mechanical Engineers (Informal Meeting), at 7.—R. Borlase Matthews and others: Discussion on Engineering in Agriculture.

Iron and Steel Institute (jointly with West of Scotland Iron and Steel Institute) (at Royal Technical College, Glasgow), at 7.15.—J. H. Andrew, W. R. Maddocks, D. Howat, and E. A. Fowler: The Equilibrium of Certain Non-Metallic Systems.—B Matuschka: The Solidification and Crystallisation of Steel Ingots: the Influence of the Casting Temperature and the Undercooling Capacity of the Steel.

Hull Association of Engineers (at Municipal Technical College, Hull), at 7.15.—J. N. Waite: Combustion and Boiler-house Efficiency.

Society of Chemical Industry (South Wales Section) (at Technical College, Cardiff), at 7.30.—R. D. Owen: Chemistry of Dairy Products.

Junior Institution of Engineers, at 7.30.—S. J. Clifton: Automatic Combustion Control.

Royal Aeronautical Society (at Eton College).—The Master of Sempill: Lecture.

PUBLIC LECTURES.

SATURDAY, October 24.

Royal Institute of British Architects, at 3.—A. S. G. Butler: Tendencies in Modern Buildings.

Horniman Museum (Forest Hill), at 3.30.—F. A. Rudd: The Legacy of Antiquity.

MONDAY, October 26.

University College, at 5 30.—Prof. G. M. Trevelyan: The Call and Claims of Natural Beauty (Rickman Godlee Lecture).—K. de B. Codrington. Indian Sculpture.

University of Leeds, at 8.—Prof. B. A. McSwiney: Our Daily Diet.

TUESDAY, October 27.

University of Bristol, at 5.—Dr. A. L. Flemming: The Partnership between Anæsthesia and Surgery (Long Fox Lecture).

London School of Economics, at 5.—Prof. E. Cammaerts: The Development of Belgian Culture.

University College Hospital Medical School, at 5.15.—Prof. C. R. Harington: The Chemistry and Functions of the Thyroid Gland. (Succeeding Lecture on Nov. 3.)

King's College, London, at 5.30—Sir Bernard Pares: Russian History to 1861: Break-up at Kiev: Migrations; the Tartars.

University College, at 6.30.—S. J F. Philpott: Fluctuations in Human Output. (Succeeding Lectures on Nov. 3 and 10.)

WEDNESDAY, October 28.

Royal Institute of Public Health, at 4.—Prof. F. J. Browne: The Health of the Expectant Mother.

THURSDAY, October 29.

University College, at 2.30.—Miss Margaret A. Murray: Egyptian Sculpture.

Science Museum, South Kensington (in connexion with the Exhibition of Modern Technical and Artistic Glasses), at 4.45.—Dr. W. M. Hampton: Recent Progress in Optical Glass.

B.M A., at 5.15.—Dr. F. J. McCann: The Prevention of Cancer (Chadwick Lecture).

King's College, London, at 5.30.—Dr. Eveline Martin: West Africa of To-day: Northern Nigeria; the Moslem Walled Towns of Kano, Zaria, and Katsina; Camels, Traders, and Travellers.

SATURDAY, October 31.

Royal Institute of British Architects, at 3—H. B. Creswell: The Uses of an Architect.

Horniman Museum (Forest Hill), at 3.30.—J. E. S. Dallas: A Naturalist in Western Cornwall.

ANNUAL MEETING.

October 31 to November 2.

International Society of Medical Hydrology (at American Hotel, Amsterdam).—Discussions on the Influence of Chill in the Causation of Disease, opened by Profs. Schade and van Loghem, and on Factors in Marine Treatment, opened by Prof. Moll and Dr. Haberlin.

CONFERENCE.

November 16 to 21.

International Conference on Bituminous Coal (at Carnegie Institute of Technology, Pittsburgh, U.S.A.)—Subjects for discussion:—Coal as Locomotive and Steamship Fuel, Coal in the Electric and Gas Industries; Competition of Coal with other Fuels in Heating Buildings; Coal in the Metallurgical Industries, Coal and its By-products in the Chemical Industries, Problems of Coking; Origin and Classification of Coals; Cleaning and Preparation; Mechanism of Combustion, Pulverised Coal; Relationships of Coal, Oil, and Natural Gas; Coal versus Water Power; Hydrogenation and Liquefaction of Coal; Fertilisers from Coal; Economics of Low Temperature Carbonisation; Storage and Weathering of Coal; Smoke Abatement; Stream Pollution.

The International Institute of Agriculture.

NOTWITHSTANDING the position of science in the life of the nation, little or nothing has been done by the administration of Great Britain to give 'a square deal' to the scientific and technical officers employed in the service of the State. Frequent references to the disabilities under which the specialist officers labour have been made in these columns; and whenever suitable opportunity occurs we shall continue to associate their cause with that of efficient administration. Readers of this journal will recall the recent discussion of the report of the Royal Commission on the Civil Service, when a number of proposals for reform were advocated (NATURE, Aug. 8 and 15, 1931).

Two things are needed to hasten these reforms. In the first place, an informed public opinion must be created which will insist that all important questions of the day involving scientific considerations are discussed with the full assistance of experts, who, moreover, must have free access to the supreme authority represented by the Minister. In this way the specialist officers will take their proper share in the formation of policy. In the second place, every blunder in administration which might have been avoided by the proper utilisation of scientific knowledge should receive the widest publicity.

A striking example of the maladministration of a scientific question has recently been brought to light by the publication of a detailed account of the founding, organisation, and administration of the International Institute of Agriculture at Rome.* This is the work of Dr. Asher Hobson, who for some years resided at Rome as the representative of the United States on the Permanent Committee of the Institute.

The inception of the International Institute is associated with something approaching romance. In 1884, a successful Californian merchant, the late Mr. David Lubin, bought a farm. To his intense surprise, the business ability which made him a successful merchant failed him entirely in the work of crop production. He became perplexed and at once set on foot an inquiry into the causes of his failure. This led to the study, among other things, of such subjects as railway freights, tariffs, and statistics of the area, yield, prices, and stocks of products like wheat. Eventually the idea took shape in his mind of an international organisation which would provide the farmer with all the essential information as to the world production of agricultural staples. Instead of being a blind producer and seller of some raw product like wheat, he would be in possession of the main factors of the great producing and distributing industry of which he is a unit.

---

* The International Institute of Agriculture (An Historical and Critical Analysis of its Organisation, Activities and Policies of Administration). By Asher Hobson. Pp. vii+356. (Berkeley, Calif.: University of California Press, 1931.)

Lubin then proceeded as a private individual to Europe to place this idea before its governments and rulers. He was fortunate in obtaining the interest and support of the King of Italy. An international meeting was called at Rome to discuss the question, and in 1905 a Convention, establishing an International Institute of Agriculture, was agreed to by the nations. One of the main objects of the new undertaking, as stated in the Convention of 1905, was to " collect, study and publish as promptly as possible, statistical, technical or economic information concerning farming, both vegetable and animal products, the commerce in agricultural products, and the prices prevailing in the various markets, and to communicate to parties interested, also as promptly as possible, all the information just referred to ".

The various chapters of Dr. Hobson's book make melancholy reading. After the inspiring account of the personality of Lubin, it is sad to trace the gradual decline of the Institute as the inevitable consequence of unsound principles of organisation and of administration. Although a scientific institution, the man of science has from the very beginning not only been denied opportunities in direction but also has been relegated to a subordinate position. The direction of the Institute has failed to take note of the fact that the universities of the world for many years past have provided numerous examples of the successful administration of scientific work, and have never failed to attract and to retain talent of the first order.

Instead of following the well-tried methods of the great republics of learning, those responsible for the conduct of the International Institute of Agriculture have attempted other methods of getting things done. The members of the *corps diplomatique* and the retired Civil servants who have been in charge of the movement have, with the valour of ignorance, applied the conventional methods of departmentalism both to the organisation and governance of a scientific institute. The result has been a tragic failure, in spite of the recent efforts of the representatives of the United States and Great Britain on the Permanent Committee in obtaining funds for the development of the work and in urging reform. One after another the scientific men, who at the beginning were attracted to the movement, have resigned in despair. Instead of specialising in statistical work, and so making an honoured name for itself in international effort, the resources of the Institute from the very beginning have been thinly spread over a vast number of projects, none of which has been effectively handled.

The library of the Institute has been neglected, in spite of a generous provision for staff and equipment supplied by well-wishers in America. The publications can only be described as deplorable. Perhaps, however, the worst feature of all is the attempt in recent years to make programmes take the place of research. The most glaring example of this is the creation of the International Scientific Agricultural Council, consisting of 23 separate Commissions, with more than 600 members. The actual result so far accomplished has consisted in the holding of one meeting—in November 1927—and the issue of a vast programme covering the whole of agriculture, the conclusions alone of which occupy no less than 75 printed pages. It bears no relation whatsoever to the actual resources and work of the Institute.

In the last chapter of his book, Dr. Hobson deals with the future and with the reforms which must be adopted if the Institute is to fulfil its proper functions and become an important and effective body in the world's agriculture. This matter is dealt with in the following words:

> " The Institute represents many peculiarities but perhaps none is so peculiar as the fact of its being a scientific organisation without a scientific staff. . . . It is safe to assert that the Institute will never be able to satisfy expectations until the Permanent Committee faces the task of recruiting a highly trained technical staff, thereby enabling the bureaus to turn out information of a reliable and usable variety. This task has always been relegated to the background on the basis of lack of funds, but it is suggested that the present salary budget distributed over fewer and carefully selected individuals, would go a long way in accomplishing the desired result. The fact that funds are limited makes it more urgent that unproductive employees be eliminated. To attempt to conduct a scientific institute without scientific and technical leadership is akin to the maintenance of a hospital without doctors, surgeons or nurses."

The present complex system of government consisting of a Permanent Committee and of an Assembly should be simplified. A scientific man, of the necessary standing, assisted by a properly trained staff, should be appointed for the future conduct of the Institute. If this were done, the prospects of future development would be much more promising than they are at present.

Our Mathematical Ancestry.

A Manual of Greek Mathematics. By Sir Thomas L. Heath. Pp. xvi + 552. (Oxford: Clarendon Press; London: Oxford University Press, 1931.) 15*s.* net.

It is scarcely necessary to introduce the reader to an author so well known and so distinguished for his writings upon Greek mathematics. Among those who are fortunate enough to have learnt something of the wonder and liveliness of ancient geometry, a new book by Sir Thomas L. Heath is always hailed with delight. On the other hand, there are doubtless many who may be tempted to think that, amid the distractions and interests of present-day science, it is a vain thing to spend time in reading up history of such a distant past. There is presumably enough to engage the attention of the most active mind in acquiring a working knowledge of current methods in mathematics or mathematical sciences. This is, of course, a mistaken idea: from the point of view of gaining proficiency in technique alone, there is much value in cultivating mathematical style, just as the young artist is encouraged to study the work of the early masters: and no boy plays worse cricket from watching Hobbs bat. Greek arithmetic, Greek algebra, and Greek geometry were all wrought by men of genius, who were working in a material of not too intricate a texture, so that an intelligent reader, with only the rudiments of mathematics, can follow their arguments without a long apprenticeship. It is therefore a boon to have a book which gives unstintedly an account of these early centuries, and enables a student to read for himself of the doings and discoveries of Euclid and Archimedes.

As the author remarks in the preface, the book is not written for experts, but for the student and the general reader who has not altogether forgotten his school mathematics. The treatment is straightforward and complete, giving a very judicious choice of interesting or important material, without the inevitable tedium of long preliminary proofs covering special cases. In the background is the sanction of a lifelong study of the documents: and the reader feels that he has been put in living touch with the men who fashioned mathematics. Here, for example, is the work of Euclid, no longer diluted, improved, or misunderstood, as the case may be, but given as it actually was. Whatever may be the defects of the " Elements " as a school textbook in geometry, the present reviewer is grateful that in his boyhood Euclid was still taught at school. How came it about that a Greek, of the name of Euclid, wrote a textbook which in an almost literal translation was used in our schools and colleges as the one recognised basis of instruction in elementary geometry until some thirty years ago? The author addresses himself to answer this interesting question.

The present manual, which gathers into one volume the substance of earlier works by the same author, begins with an account of the origins of western mathematics in Babylonia and Egypt: it ends with the relatively undistinguished minor characters, of the sixth century of our era, who succeeded Diophantus, renowned for his algebra, the last great representative of the Second Alexandrian School. In recounting this impressive story of so many ages, the author has given himself a free hand, and has appeared in the rôle not so much of the cautious historian (which scarcely needs saying), but as that of the teacher or expositor who adds the suggestive touch that makes the picture live.

The book has its passages of special interest for the expert, as it embodies several notable and recent discoveries. The romantic discovery in 1906 of the "Method" of Archimedes in a Constantinople palimpsest has thrown light upon a perplexing problem: How did the Greeks find out their results? In the finished pages of Euclid or Archimedes, just as in the published results of Gauss, there is little to show the beginning of the quest—the guesses, conjectures, and tentative arguments which gave way to the final proof. But not until the "Method" was found by Heiberg was any light thrown upon the problem. In the present " Manual " we have considerable details of this newly found document. As Sir Thomas has remarked in his earlier " History ", it incidentally establishes Democritus as a pioneer in the integral calculus, for he was the first to state correctly the formula for the volume of a cone. Archimedes confesses that he discovered the analogous formula for the area of a parabolic segment by weighing it, theoretically or practically. At any rate, the theoretical proof might have come out of a current textbook on statics, illustrating the theory of moments and centroids with both elegance and precision.

Another passage of interest concerns Egypt and Babylonia. Recent exhaustive investigations of the Rhind Papyrus (by Prof. T. E. Peet in 1923 and Mr. Arnold B. Chace in 1929) have made the facts far more accessible than they were at the time when the " History " was written. Something of the yet unpublished Moscow Papyrus of the Twelfth Dynasty has also been included, and all this has greatly increased the prestige of Egyptian mathematics.

While it is still true that nothing comparable to a general proof has yet been found among all the Egyptian writings, more and more *ad hoc* formulæ are continually being brought to light; and some of these are very remarkable, such as the arithmetical instances which strictly illustrate the formula $V=\frac{1}{3}h(a^2+ab+b^2)$ for the volume of a truncated pyramid with parallel square faces whose sides are a and b: or again the still more remarkable formula

$$S=\{2d-\tfrac{1}{9}\,.\,2d-\tfrac{1}{9}\,(2d-\tfrac{1}{9}\,.\,2d)\}\,.\,d$$

for the surface of a hemisphere whose diameter is d (Moscow: Problem 10). If this is worked out, $S=2\,.\,\frac{256}{81}\,.\,r^2$ so that it gives 256/81 as the value of π, a very good approximation.

Even more wonderful is the state of mathematical science in Babylon, as it now appears in the light of the most recent discoveries. We are led to infer from the inscriptions that the Babylonian surveyor of 2000 B.C. had little indeed to learn from the modern practical textbook on quadratic equations. Not only was a sexagesimal number notation in vogue—involving a multiplication table up to 59 × 59 and the position-value system—but also a formula for the solution of quadratic equations was employed. For example, if

$$\xi^2-\frac{2d\alpha}{\alpha^2+\beta^2}\,\xi=\frac{A-d^2}{\alpha^2+\beta^2},$$

then

$$\xi=\frac{1}{\alpha^2+\beta^2}\,[d\alpha+\sqrt{\{d^2\alpha^2+(\alpha^2+\beta^2)(A-d^2)\}}].$$

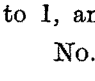
An inscription actually gives the detailed evaluation of this formula, with $A=1000$, $d=10$, $\alpha=40$, $\beta=60$. Examples of parametric bilinear equations in two unknowns, leading to a quadratic in one unknown, are also solved.

A few of the many passages of interest in the account of the Greeks may also be mentioned. On p 27 appears a diagram of an abacus—no ordinary abacus, but something of a riddle. Its likeness to the full musical stave, with eleven lines, five for treble, five for bass, and one for middle C, may be a coincidence, but there it is.

The beautiful proof of the identity

$$1^3+2^3+\ .\ .\ .\ +n^3=\{\tfrac{1}{2}n(n+1)\}^2$$

by Nicomachus is duly given. The series is equal to $1+(3+5)+(7+9+11)+\ .\ .\ .$, but this neat result is certainly not told in all the ordinary textbooks, on algebra, where surely it should have place. Border one small square with three equal squares and again with five, making $1+(3+5)=3^2$: a gnomon has been added to 1, and this gnomon is the cube of 2. Nicomachus proves the identity by adding the general gnomon after n terms, and by so doing he provides a genuine example of mathematical induction.



The author has sacrificed nothing (and has made the pages much easier reading) by exhibiting results in our familiar algebraic notation, as in the above Babylonish examples. Each formula is justified by the context.

The book is well printed and does credit to the publishers, who have performed their work most attractively. Considering its scope and contents, the book is reasonably priced, and is likely to be widely read.

H. W. TURNBULL.

Physical Anthropology of the American Indian.

The Indians of Pecos Pueblo: a Study of their Skeletal Remains. By Earnest Albert Hooton. Appendix on the Dentition by Habib J. Rihan; Appendix on the Pelves by Edward Reynolds. Statistical and Laboratory Assistants: Ruth Otis Sawtell, Ethel Clark Yates, Pearl B. Hurwitz. (Papers of the Southwestern Expedition, No. 4.) (Published for the Department of Archæology, Phillips Academy, Andover, Mass.) Pp. xxvii + 391 + 112 plates. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1930.) 56*s.* net.

IT is not always sufficiently realised to what extent a study of the early history of man in the New World may throw light on the early history of man in the Old World. No doubt this arises from the fact that many anthropologists are content with the assumption that all the aboriginal inhabitants of America were from first to last Mongoloids. But " the theory of the originally and perpetually Mongoloid character of the American population is difficult to accept in view of the decidedly non-Mongoloid character of the stratigraphically early types ". This opinion, quoted from the last paragraph of Dr. Hooton's elaborate and carefully prepared monograph, indicates one of the central problems which are presented as a result of his ten years' study of the skeletal remains of the Indians of Pecos.

The ruins of the Indian pueblo of Pecos lie on an easily defensible site in the valley of the Pecos river in central New Mexico. The village was visited by the first Spanish expedition which penetrated south-west in 1540. In 1620 the population is reported to have been about two thousand. The historical period of the village lasted until 1838, when the remaining twenty inhabitants of Pecos migrated. On the basis of stratigraphy and pottery sequence, it was possible to recognise six periods in the life of the settlement of Pecos since its foundation about A.D. 800. Of these, four periods belong to the prehistoric phase, that is, prior to the date at which the natives came into contact with Europeans. The excavations of the ruins have clearly been carried out with the utmost scientific precision and only skeletal material of undoubted provenance and in good preservation has been included in the series upon which Dr. Hooton has based his study. We are impressed, therefore, with the suitability of the Pecos material for a study of the physical nature of the American Indian population before it became in any way affected by post-Columbian migrations.

Dr. Hooton's treatment of his unique osteological collection is eminently scientific. He is aware of the limitations of physical anthropology so far as skeletal material is concerned, and he is careful to distinguish clearly between legitimate deductions from ascertained facts and speculative considerations. In estimating the age and sex of the material, he has had the assistance of Prof. Wingate Todd. It is instructive to note that in the sexing of 264 complete skeletons, these two authorities (both of whom are to be regarded as experts in their subject) disagreed in 15 per cent of cases. To those less experienced anthropologists who are not aware of the difficulties of sexing a skeleton, even when the pelvis is intact, this result will appear surprising. Another interesting fact is that the inhabitants of Pecos seem not to have varied their stature over a period of a thousand years, in spite of the fact that since the Spanish intrusion there was a gradual extinction of the population through war, disease, and probably famine and malnutrition.

Most of the present volume is devoted to the craniology of the Pecos Indians, a study which was complicated by the fact that only 40 crania out of a collection of 615 showed no trace of artificial deformation. Dr. Hooton was able to distinguish a number of morphological cranial types, which he distinguishes as "Basket Makers", "Pseudo-Negroids", "Pseudo-Australoids", "Plains Indians", "Long-faced Europeans", "Pseudo-Alpines", etc., but at the same time he finds no evidence that any "new race" appeared during the history of Pecos. The question remains as to how far these cranial types represent valid morphological types and not the artificially selected extremes of a homogeneous but very variable group. The author believes that the former interpretation is correct, and his statistical evidence certainly seems to confirm this conclusion. He further illustrates his types by a series of photographs made by the superimposition of images of a number of skulls of the same type on the same negative. We think this method of composite photography to be not very sound. An examination of the composite photographs makes it clear that the impression produced on inspection is not that of an 'average' skull. In the contour outline of the skull as a whole, for example, the photograph, by its method of production, tends to lay much more stress on the smaller contours and more restricted outlines of the group. We should have been happier to have seen average contours constructed on the basis of actual measurements, as has been done so successfully by Parsons and others in Great Britain.

It is in the discussion of the affinities of these morphological types that Dr. Hooton especially attracts our interest. The Basket Maker type is very similar to the Basket Maker crania of Arizona, and also bears a strong resemblance to crania of the so-called Mediterranean race. Indeed, "in indices the South-western American crania are so similar to the crania of Egyptians as to be well-nigh identical". The author thinks, however, that we cannot go beyond the inference that "the Basket Maker and Ancient Egyptian groups represent divergent off-shoots of a common primitive race which may have sent colonies in many different directions during the neolithic period". The Pseudo-Negroid type is found to differ less from the African negroes than from other morphological types in the Pecos population. This leads to the conclusion that the earlier dolichocephalic invaders of America carried with them an infusion of negroid blood which had been derived from the tropical parts of the Old World. If this conclusion is not legitimate, then it is only possible to infer that craniological variability in a homogeneous population is much greater than most anthropologists would care to admit, and that, in fact, it is a very risky business to attempt the racial diagnosis of a skull when dealing with isolated specimens.

The Pseudo-Australoid type is admittedly a misnomer and the type is found to stand very close to the Ainu, though there are significant differences. The Long-faced Europeans and the Pseudo-Alpines were likewise provisional names given to types which on subsequent analysis were found, in this case, to be related to Mongoloid types, the former showing an affinity to Eskimos in general proportions and the latter resembling crania of Tibetans, Burmese, etc.

As has been already indicated, Dr. Hooton's treatment of this material is exhaustive, and we sympathise with him when he says at last, "After traversing all of this weary waste of tables and statistical comparisons of measurements, indices, and anatomical details, I feel justified in permitting myself the luxury of expounding my present views on the anthropology and prehistory of the American Indian". Briefly, Dr. Hooton believes that his evidence indicates a migration by way of the Bering Straits into the New World, soon after the retreat of the last glaciation, of a mixed group of dolichocephals containing a Mediterranean element, a Negroid element, and a more primitive element represented in part by the Ainus of Japan. At a later period, the Mongoloid invasion of the New World took place and the invaders either supplanted or interbred with their predecessors.

This is an attractive theory and one of fundamental importance to students of Old World prehistory, for its acceptance must inevitably affect current ideas regarding the distribution of non-Mongoloid races in Asia during late Palæolithic and early Neolithic times. Further, Dr. Hooton's conclusions provide an additional and rather interesting basis of argument for those ethnologists who maintain that there was abundant contact between the Old and New Worlds in pre-Columbian epochs. This point of view, however, is not touched upon by Dr. Hooton, somewhat to our disappointment.

We heartily congratulate Dr. Hooton on the production of this monograph on the physical anthropology of the American Indian. If, as he himself says, the study of this subject is still in its infancy, the result of his work of ten years has done much to bring it towards maturity.

W. E. Le Gros Clark.

Organic Chemistry.

An Introduction to Organic Chemistry. By Prof. John Read. Pp. viii + 365. (London: G. Bell and Sons, Ltd., 1931.) 6*s.* 6*d.*

We confess this book makes a strong appeal to us: it approaches our ideal of how organic chemistry should be taught to that difficult person, the student—whose primary interest lies in other fields in which, if he only knew, he will make real progress only with difficulty unless his understanding of what to-day is comprised in organic chemistry is substantial.

Prof. Read is happy at the outset in his extract from that famous book of Mrs. Marcet on which we are told Faraday was nurtured. Organic chemistry is not a mass of dry facts or confined to analytical minutiæ; it is the livest of all sciences, full of unexpected and exciting happenings, and yet withal the game is played according to a set of rules based on molecular structure; rules which, elaborated in early days by Frankland, by van 't Hoff and Le Bel, by Kekulé, still prevail to-day; rules which have permitted us to glimpse at the inner structure of the sugars with Emil Fischer, of chlorophyll with Willstätter and porphyrins with Hans Fischer, of the alkaloids with Perkin, of the anthocyanin colours of plants with Robinson. Mrs. Marcet well said that "Nature also has her laboratory, which is the Universe". It is a happy inspiration of the author to develop aliphatic chemistry round the fats, the carbohydrates, and the proteins and to proceed to the closed chain aromatic, alicyclic, and heterocyclic compounds, treating them on the broadest lines. Actually the book contains the subject matter of a series of thirty lectures and it is interspaced with lecture experiments. A number of questions appear at the end of each chapter. There are several simple illustrations, a number of clear tables, and an ample index appropriately introduced by an extract from "Caroline's Conversations". We have special praise for the formulæ, which are not unnecessarily elaborate, whilst judicious use is made of heavy type.

We are not too satisfied with the author's repeated use of the term 'nucleus' for the carbon skeleton of a number of compounds. It is true that this is habitually used by chemists to distinguish the aromatic part of benzenoid from the side chains, so that he has some justification for the extension of the term, but to us the word nucleus does not imply a chain of carbons and we prefer the more usual words skeleton, grouping, or unit; this, however, is a very minor criticism of a successful attempt to make clear to the student how characteristic and how common certain arrangements of carbon atoms are.

It is surprising how much information has been included in so small a compass as the result of leaving out the old and, to the student, uninteresting details of preparation and reactions; space is even found to embody much information in relation to the utilisation of the compounds in practice and industry. Prof. Read has certainly succeeded in catching the spirit of the subject, and we shall be disappointed if students do not find his book inspiring.

E. F. A.

Short Reviews.

The Vitamins. By Prof. H. C. Sherman and S. L. Smith. (American Chemical Society Monograph Series, No. 6.) Second edition. Pp. 575. (New York: The Chemical Catalog Co., Inc., 1931.) 6 dollars.

MORE than nine years have elapsed since the previous edition of this American Chemical Society Monograph was reviewed in NATURE (vol. 110, p. 6, July 1, 1922). This second edition contains 349 pages of text and about 3000 bibliographic references; the corresponding figures for the first edition were 234 and 1000.

During the intervening period, 'fat-soluble A' has been split into vitamin A proper and the antirachitic vitamin D: the latter has been prepared photo-synthetically and obtained crystalline, though not pure, in two laboratories independently; vitamin E, essential for rats and some other animals to prevent resorption of the fœtus by the pregnant female and degeneration of the spermatogenic tissue in the male, has been discovered and styled the anti-sterility vitamin; vitamin B has been split certainly into two, probably into four and possibly into five or more different factors; of these, B_2 has been generally credited with the prevention of pellagra; vitamin B_1, the actual anti-neuritic factor, preventive of beri-beri, has been obtained crystalline in four different laboratories. Besides this, an enormous mass of investigation, proportionately indicated by the increase in bibliographical references noted above, has been conducted into the physiology of the vitamins.

The subject has come to be a recognised part of biochemistry, with its own technique and its own specialised schools, often associated with the names of distinguished individual scientific workers. It has been recognised, indeed, by the Nobel trustees, since at least three of the workers in this field have been honoured by their award.

This book is the only one in the English language —and, we believe, in any language, with one possible exception—covering the subject as a whole. It is not a popular exposition, but a technical monograph in the strictest sense, and of the highest order of excellence. It is indispensable to all concerned in any way with nutritional problems and to all biochemists, and should also be so to the majority of physiologists and to many medical men.

A. L. B.

Measures of Double Stars. By Prof. Francis P. Leavenworth. With which are included the Measures by William O. Beal. (Publications of the Astronomical Observatory, University of Minnesota, Vol. 1.) Pp. viii + 111. (Minneapolis: University of Minnesota Press, 1930.) 5 dollars.

THIS volume is published as a memorial to Prof. F. P. Leavenworth, who died in 1928. It contains the annual means of his observations of 1185 double stars, made between 1886 and 1927. They were made chiefly with the 10½-inch refractor of the University of Minnesota, but some were made at Yerkes, Haverford College, Leander McCormick, and Goodsell Observatories. Many stars that show motion have been followed regularly; thus Castor (*AB*) was observed forty-five times during an interval of thirty-nine years; the distant companion *C* was also observed five times; there are forty-six observations of Sirius, and seven of Antares, which shows no appreciable change of distance or angle in forty years.

The volume contains a brief sketch of Prof. Leavenworth's life and astronomical work; an appendix gives a full list of his papers; another appendix gives measures of 289 double stars by Prof. W. O. Beal, who was instructor in astronomy at the University of Minnesota from 1913 until 1926, and assistant professor from 1926 until 1930.

A. C. D. C.

A Laboratory Manual of Electrochemistry. By Prof. Dr. Erich Müller. Translated from the fourth edition by Dr. H. J. T. Ellingham. (Twentieth-Century Chemistry Series.) Pp. xiv + 363. (London: George Routledge and Sons, Ltd., 1931.) 15*s.* net.

THE present manual deals with practical electrochemistry in more detail than laboratory works on physical chemistry, and is more suited to a special course on the subject than to the ordinary course in physical chemistry, where there is not usually sufficient time available for so many experiments on electrochemistry. It includes inorganic and organic electrochemical preparations and potentiometric titrations as well as an excellent series of experiments on the fundamental laws. Brief but very clear accounts of the theories are given, and the book will be useful in the study of theoretical electrochemistry as well as in the laboratory. The translation is good and the printing well done, although the paper is too thick for a laboratory manual and the book will not stay open on the bench. The book should be in every university and technical college laboratory for reference.

The Story of Surnames. By William Dodgson Bowman. Pp. vii + 280. (London: George Routledge and Sons, Ltd., 1931.) 7*s.* 6*d.* net.

MR. BOWMAN's popular account of the methods and material for the study of surnames will serve a useful purpose in making known a fascinating and instructive subject of investigation to a wider public. It is indeed surprising that the literature on the subject is relatively so small. Few investigations which can be so readily followed throw more light on the habits and mentality of our ancestors than the surnames they used and the reasons for which they gave them to individuals. Mr. Bowman's work is fully in accordance with accredited methods; nor does he fail to warn us by precept and by examples, which follow scientific method, of the dangers of the over-hasty conclusion which is nothing more or less than guesswork. The chapter on fourteenth century London is an excellent example of the intimate detail relating to the organisation and life of an urban population that this class of evidence can be made to yield.

On the Nature of Mind.*

By Dr. C. S. Myers, C.B.E., F.R.S.

PSYCHOLOGY was given the status of an independent Section, with the approval of the Sections of Physiology and Education, at the Cardiff meeting of the British Association in 1920. The new Section met for the first time in 1921 under the presidency of Prof. Lloyd Morgan. Thus the present centenary meeting marks also the completion of ten years' existence of our Section. I can vividly recall the doubts which were expressed, not so much in words, as in general attitude, by the Committee of Recommendations of this Association when in 1920 it was asked to consider the formation of a separate Section of Psychology. Such hesitation was probably based on several grounds, not wholly on any one of them. But some of these grounds have lost much of their force to-day, because of the pronounced change that has since taken place in the attitudes and beliefs which were in vogue among physicists of that time. No physicists would then have dared, as now, to cast doubt on the sole sway of determinism in the physical world. None of them would then have suggested, as now, the impossibility of predicting what any *individual* atom (or still smaller *individual* entity) will do next. None would have questioned, as now, the universal truth of the second law of thermodynamics or of the principle of conservation of energy. None would have ventured, as now, to suppose that electrons change in the very act of becoming known to us, and that therefore the mental factor is ultimately inseparable from physical investigations. None would then have dared, as now, to conjecture that particles of matter correspond in their properties to certain *group* waves of the ether, the *constituent* waves of which, travelling at an enormous speed, 'guide' and 'direct' the group waves without any energy of their own.

Psychology has been similarly bereft of reality by the operations of mathematicians, present and past. The earliest example of this was the derivation by Fechner of the 'law' which now bears his name, that the intensity of a sensation is proportional to the logarithm of the magnitude of its stimulus. This statement was deduced by purely mathematical procedure from Weber's law that just appreciable differences between sensations depend on a constant ratio between the magnitudes of their respective stimuli. Weber's law, however, was based on direct observation and experiment; whereas Fechner's 'law' was the outcome of purely mathematical calculations which not only neglected a constant appeal to the 'reality' of experience, but also ran actually counter to it—neglectful, for example, of the 'facts' (i) that Weber's law holds for only moderate magnitudes of stimuli; (ii) that from the point of view of conscious experience it implies a *single experience* of difference, not a *difference between two* separate experiences; and that (iii) from the same point of view we are quite unwarranted in adding together or subtracting from one another two intensities of sensation or two sensation differences as such.

Elsewhere in his treatment of psychological data, as in his treatment of physical data, the mathematician has arrived at results that can directly be neither verified nor rejected by conscious experience. The establishment of 'general mental factors', involved in and influencing the performance of various mental tests and other processes, affords us another example. By mathematical operations on experimental data we can, it is claimed, deduce the existence of such general factors. But from the strictly psychological point of view the nature of these factors cannot be interpreted; for we are unable to appeal to direct experience to ascertain what these factors are. At best their significance in terms of actual experience can only be conjectured by abstraction and imagination; or it is expressible only in terms of general behaviour. At worst, as in the case of g (the so-called 'general intelligence'), we are quite ignorant of their psychical nature. We cannot hope for direct psychological evidence as to the precise mental nature of such mathematically deduced 'factors'.

Psychology and Behaviour.

The escape from such difficulty on the physical side—so as to avoid dethronement of the literally divine claims which some mathematicians have made for the fundamental truth of their own science—is to regard the universe as constituting a vast nexus of ultra-physical and mathematical necessities and probabilities, only some of which can become physical through the further operation of the human mind. We might, perhaps, adopt a corresponding attitude towards some of the subjectively unverifiable conclusions arising from the applications of mathematics to psychological data.

In psychology an additional difficulty confronts us. We have to recognise that the data with which the 'mathematical psychologist' operates are not measurements of the fundamental subject matter of psychology—conscious mental processes. (Nor can they probably be measurements of unconscious processes, so long as the latter are regarded as mental in character.) For mental processes are not directly measurable: we can *grade* a series of conscious experiences according to their degree or amount, say of hue, brightness, loudness, pitch, temperature, extent, duration, clearness, pleasantness, etc.: we can say that one member of such a series has more or less of any one such character or quality than another member, or that the difference between two members of a series in respect to any one of these characters or qualities is greater or less than, or equal to, the difference between two other members. But the psychologist can only *measure* the amount of any conscious experience indirectly—either by reference to behaviour, that is, to the organism's *physical* response or expression, or by reference to the *physical* character of the relevant stimuli, in terms of objective standards of number, space, and time which are immediately independent of actual subjective experience.

---

* From the presidential address to Section J (Psychology) of the British Association, delivered in London on Sept. 28.

Let us remember, then, that when we are attempting to measure any mental ability or character or quality by means of a test, or series of tests, we are not directly measuring that mental ability or character or quality, but only the corresponding stimulus or the outward response or expression by which that mental ability or character or quality is manifested. We are, no doubt, justified in assuming a broad correlation between the speed, accuracy, amount, etc., of the response or expression of a mental ability or character or quality and the degree in which that mental ability or character or quality is present. Even this broad assumption, however, is sometimes unjustifiable, as in the case where too much of a given mental ability or character or quality may lead to a deterioration, and no longer to an improvement, in the corresponding performance. But we are certainly never justified in assuming that we can measure accurately any mental process by measuring its objective response —that, for example, twice the amount of the response necessarily means twice the quantity of the mental process of which the response is the expression. All that we are measuring is *behaviour* —that is to say, something largely on the efferent side, something largely physical and indescribable in terms of pure immediate experience, involving a complex of factors many of which, indeed, may be remote from those which we commonly believe we are measuring; whereas what we ultimately aim at dealing with in psychology is *experience* —the meeting point of the afferent and efferent sides.

In fact, then, the 'behaviourists' are quite right when they insist that scientific measurement is applicable only to the behaviour of the organism. Where they are quite wrong is in their assumption that conscious processes must necessarily be ousted from scientific psychology, because measurement is excluded; the truth being that, even where measurement is excluded, the possibilities of systematic observation and experiment still remain. Natural science has surely a function wider than that of merely reducing its subject matter to units of space and time. Highly valuable and deserving of the utmost encouragement as is the measurement of behaviouristic data, however helpful be the light they may ultimately throw on mental processes and their general characters, however wider be mental processes than the range of mere conscious experience, the scientific study of the mind by direct observation and experiment is never to be discountenanced or discarded.

SELF-ACTIVITY.

Just as experimental physics patiently pursues its researches into Nature, heedless of such mathematical conclusions as are not amenable to verification by experiment, so experimental psychology must realise that its progress is not primarily dependent on, however much assistance it may receive from, the work of those who fail to recognise that the fundamental subject matter of psychology is conscious experience, not conduct. Now conscious experience can only be enjoyed by the active self, namely, the 'individual' (that is, undivided) mental activity of the entire living organism. It is the fundamental function of such self-activity—by recourse to past experiences, by receiving present experiences, by foreseeing future experiences and by creating new experiences—to select from alternative responses and from alternative environments those which are most advantageous to the ever-evolving and developing organism; to secure the most suitable movements and environments and thus to help in the evolution of the organism are the prime objects of consciousness. Where, as in plants, mobility and plasticity are at a minimum, self-activity and consciousness are inappreciable. Self-activity is to be regarded as the highest, unitary integration of the directive mental (conscious and unconscious) activity of the organism.

DERIVATION OF PRESENTATIONS (OR CONTENTS) FROM FEELINGS.

Self-activity and its inherent consciousness may presumably be traced back to a stage where self and not-self are but just distinguishable. At this remote stage in animal evolution there can scarcely have been more than a differentiation of self-activity into 'acts' of the self and 'modifications' of the self. These modifications of the self became early differentiated into (*a*) those which are due to internal happenings within the organism, and (*b*) those which are due to more variable external happenings in its environment, and later into (*a*) those which we come to recognise as 'affects' *of* the self and 'feeling tones', and (*b*) those which come to be regarded as 'presentations' *to* the self or as 'contents' of the self's consciousness. Sensations, perceptions, memories, and thoughts—all that we finally come to recognise as conscious *presentations* to the self—have been differentiated (onto- and phylo-genetically) from modifications of the self: instead of being *feelings* of the self, they have become *contents* of consciousness.

We end by 'projecting' certain of these original feelings. The external 'objects' of our perception have been separated from or carved out of originally vague external 'situations', of which we or our remote ancestors were first conscious merely as diffuse modifications or feelings of the self. So, too, any colour or sound comes to be regarded no longer as a self-feeling but as a something projected and existing outside us. The degree to which such projicience and presentation is carried out varies with different sensations: colours clearly have a projected, apparently independent, existence; sounds, smells, tastes, hardness, and temperature are only imperfectly projected; the painful prick of a pin and our sensations of movement, though not projected, are nevertheless regarded as 'presentations' to the self; whereas our experiences of visceral sensations are scarcely even presented:

they seem almost as clearly modifications of the self as are our emotions and other affects.

ORIGIN OF ACTS AND CONTENTS.

This difference between the acts and the contents of consciousness — between the conscious *acts* of apprehending, recalling, deciding, inferring and *what* is consciously apprehended, recalled, decided, inferred—is a most important one. It is exemplified in the two kinds of memory which are distinguishable. On one hand, we may recall the *separate acts* of the self, say, in the course of solving a problem or of acquiring some specific skill; these are individually unique and only individually revocable. On the other hand, we may recall the *generalised contents* of our consciousness, that is, of presentations we have received by a repetition of such acts, for example, in learning a prose passage or series of skilled movements.

I would suggest that the distinction between conscious acts and contents has come about with the gradual differentiation of higher and lower levels of mental activity—and in the following manner. There is no awareness of self-activity when we sense a colour or a temperature, or when we perceive a familiar object, or when an idea 'occurs' to us. Our sensations, our perceptions, and many of our thoughts and ideas are, I suggest, the unconscious 'acts' of relatively lower mental levels. But when these lower-level 'acts' are accompanied and received by the self-activity of the highest levels, they become *ipso facto* 'presentations' to the self. A loud noise to which we are impelled to attend or an idea which 'occurs to the mind' is not a conscious presentation (or content of consciousness) until the self receives it.

I suggest that such differentiation of higher and lower levels has never occurred to the same extent in the case of our kinæsthetic and, especially, cœnæsthetic sensations and in the case of our feelings (which depend on a more primitive, thalamic, activity): we fail, therefore, to objectify them immediately as presentations, and they continue to be received in their primordial undifferentiated state.

UNCONSCIOUS DIRECTION AND PURPOSE

The self is the highest controlling and directing power. The orders which it consciously gives and the efforts which it consciously makes may, once started, continue to be carried on unconsciously, that is, without the conscious participation of the self. Thus we may consciously but vainly try to recall some past experience or to solve some difficult problem; and after giving up the effort, this directive activity may still persist unconsciously until suddenly the forgotten object, or the abandoned solution, suddenly flashes full-born and unbidden into the self's consciousness. So, too, we may go to sleep determined to wake up at a given hour, or we may accept, in the hypnotic state, a decision to carry out some prescribed act on the lapse of a prescribed period of time after emerging from that state; and at the ordained moment the sleeper wakes, or an uncontrollable impulse is felt to perform the suggested act.

Not only is purposive activity not limited to th duration of conscious activity but also it need no originate there. The inspirations of genius an the intuitive judgments and decisions which, crud though they may be before submission to the self' judgment, arise apparently from the 'depths' o the mind with impulsive force and compelling conviction afford striking examples of this fact. Th well-known improvements in learning which continue after we have ceased to practise, so that i has been said of us that we learn to skate in summe and to swim in winter, are further examples of suc activity—whether or not we choose to ascribe suc improvement to the gradual disappearance of adverse initial inhibitions or to the direct strengthening ('consolidation') of acquired integrations (o associations).

Further, the self is continually being played upo both by the impulsive and by the perseveratin forces of lower mental systems. They struggle, no less than the self, for their own existence and fo their own lower 'self-ish' ends. Where they ar modified by inhibition (or repression), it is only t ensure general harmony and general compatibility Inhibition is not to be viewed as a mere act o passive drainage of energy from one mental constellation to another, but as an active repressiv force against which the inhibited constellation eve tends to rebel in its endeavour to gain somehow o another liberty of action, in some lower degre purposeful and directive.

CEREBRAL LOCALISATION OF CONSCIOUSNESS.

While consciousness always implies self-activit and while the self is to be regarded as the expressio of the highest level of mental activity, we mus guard against the notion that such high-leve activity implies a narrowly limited zone of menta processes. On the contrary, it implies a wid sphere of activity rather than a punctate, pineal gland-like soul. It follows, therefore, that w cannot hope to localise any act or any content o consciousness in one small region of nervous substance. Afferent-efferent localisations of functio undoubtedly occur—regions where the incomin impulses become deflected to outgoing processes our knowledge of the physiology and structure o the spinal cord clearly points to this. Sensori motor localisations may, in a sense, be said to exis similarly in the brain. The occipital region of th cerebral cortex, for example, is concerned wit vision. But because vision ceases when the *are* *striata* in this region of the cortex is injured, we ar not justified in saying that this area is the *seat* o centre of our visual consciousness. All that we ar warranted in concluding is that it is *essential* for ou visual consciousness, that without it vision is impossible—a very different statement.

Once again, let me repeat, consciousness implie self-activity. There are no separate loci for different kinds or modes or qualities of consciousness The nervous system and the system of self-activit work as a widespread unity. Different regions o the brain are more particularly concerned in *givin* *rise* to certain kinds of consciousness. The thala mus, for example, is especially concerned with the emotional consciousness; but we are not justified in calling it the *seat* or centre of such consciousness.

We are, in fact, neither warranted in supposing that there are definite seats or centres of sensation or emotion, nor justified in supposing that our manifold percepts, images, or ideas each have their seat in different narrowly localised centres of the brain. A similar truth holds for the association (or integration) of such experiences. We can *mentally* picture an integration of two 'patterns' of conscious activity occurring when two experiences *a* and *b* follow one another repeatedly, so that when *a* is later given, *b* (or rather the whole *a–b*) recurs; but *neurologically* we can form no simple corresponding picture of two collections of nerve cells being associated together. We have no evidence to support such cerebral localisation of association areas; indeed such experimental evidence as we have is against it.

Even if there were no evidence pointing in one direction or the other, how could such localisation of memories and habits possibly occur? Consider the babe that is learning to associate its mother with the satisfaction of its hourly wants. Its mother is never twice the same—now in one dress or facial expression, now in another; and the visual image of the mother received by the retina is never twice the same—for example, sometimes the mother is very near, sometimes farther off; sometimes the image falls on one part of the retina, sometimes on another. How can we imagine, then, any definite collection of retinal or cortical nerve cells responsible for developing the image of 'mother'? What develops is surely rather a 'meaning'—a generalisation of images, 'standing for' something, that is, for the assuaging of certain needs, for the execution of a wide range of adjustments of the infant.

Relationships and meanings are therefore the all-important mental acquirements. The acquisition of such relationships is shown, for example, in the many experiments conducted on a large variety of species, high and low in the animal scale, where by long practice the organism is trained to enter *B*, the brighter of two alternative compartments, *A* and *B*, in order to reach its food. When later, in place of *A* and *B*, *B* and *C* are substituted, *C* being now brighter than *B*, does the animal go to *B* to which it had previously been trained to go? Generally, no. It enters the *C* compartment. That is to say, it has learnt to enter not a *particular* compartment, but the *brighter* of any two compartments. It has not learnt to select a 'particular' object. It has learnt a 'relation'. Surely evidence of this kind is contrary to any atomistic localisation of individual mental functions in separate cerebral areas.

RELATION BETWEEN DIRECTIVE AND MECHANICAL ACTIVITY.

The fundamental purpose of consciousness is to enable the self to preserve the organism by guidance and direction—by the formation and satisfaction of ends and values. As in the evolution of living species something far more is involved than the mere blind running down-hill of a wound-up mechanism, so in the mental and bodily life of each organism the physical conceptions of 'entropy' and of mechanical energy are inadequate. On the physical side we can form no conception of the mode of working, throughout life and mind, of anything resembling Clerk Maxwell's directive 'demon'. Physiologically, that is to say, physically, the brain-worker should need food with a far lower caloric value than he actually takes and requires for the successful maintenance of his purely mental activities. But, in fact, mental work appears to make far greater demands on metabolism than it should according to purely physical considerations of the expenditure of mechanical energy.

At present we can form no conception of the nature of the undoubted connexion between chemical metabolism and direction in the living organism —between senility of body and senility of mind, between the rise and decay of procreativeness and the rise and decay of the creativeness of genius. At present we can form no bridge between mechanical and creative, directive activity. We can only say that both activities are essential to a conception of the evolution and working of life and mind. Mental activity involves a quintessence of the non-mechanical, directive activity of life; and consciousness is but that activity raised to its highest power. Even lower-level mental and neural systems, even the activities of the lowest living organisms, are characterised by unconscious creation, direction, guidance, and purpose in varying degrees. But conscious creation and direction, the consciousness of *acts*, is limited to the highest-level psycho-neural activity—the self.

I have suggested above that, when the physiological activities of the lower-level systems meet with the highest-level activities, they may become manifest as conscious *presentations*; these highest-level activities are, I believe, to be regarded as arising from the supreme organisation and distillation of the directive activities of the living organism. The acts at this highest mental level constitute the purposeful, directive, creative, and contemplative self, and are the recipients of presentations from lower cortical, and also of feelings from lower, primordial, thalamic activity.

The psychologist's principle of the *conservation of self*, which corresponds to the biologist's inevitable principle of the *struggle for existence*, is the fundamental function of this conscious activity. It is as real and important as the physicist's principle of *conservation of energy*. We must leave to the future the task of bridging the present impassable gulf which yawns between these two principles. Meanwhile let us always remember that blind mechanism in the material world is a truth not more fundamental than the reign of guidance, creation, and purpose in the world of life and mind, and, it may well be, throughout the universe; indeed, our very notions of these two principles, governing perhaps both the living and lifeless world, appear to be the outcome of, even if they do not wholly depend upon, the experiencing, reasoning, and imagining self.

Ultrasonics: Some Properties of Inaudible Sound.*

By Prof. F. LLOYD HOPWOOD.

THE intensity or loudness of a sound depends upon the extent or amplitude of the vibration set up, and its pitch upon the frequency or number of vibrations per second. Disturbances of the same type as sound waves may be inaudible either because the intensity (loudness) is insufficient or because the ear is deaf to those particular frequencies: the normal range of hearing of a human being extends approximately from 20 to 20,000 vibrations per second.

'Sounds' of higher frequency than 20,000 are called supersonic or ultrasonic. They can be generated in a variety of simple ways, as, for example, by rubbing a resined rag along a steel wire or by tapping the end of a short rod of material with a suitable hammer; thus, a steel rod 10 cm. long, clamped at its middle point and tapped at one end, will emit an inaudible 'note' of 26,000 vibrations per second, and when two steel balls 1 in. in diameter collide, they vibrate after impact at the rate of more than 100,000 vibrations per second.

Such ultrasonic emission is discontinuous, of feeble intensity, and is accompanied by parasitic audible sounds. The most convenient generator of sustained vibrations is the valve-oscillator. The vibrator itself is a disc of natural quartz crystal cut with its plane faces parallel to its optic axis and at right angles to an electric or binary axis. Such a disc was shown by MM. Pierre and Jacques Curie to possess the remarkable property that when it is compressed its faces become oppositely electrified, and that its electric charges become reversed in sign if the disc is subjected to extension instead of compression. Periodic reversal of stresses is immediately followed by periodic reversal of electrification. Prof. Pierre Curie also showed that natural quartz, in common with certain other crystals, possesses the converse property, namely, that if the opposite faces of a suitably cut disc are electrified, the crystal contracts in one direction and expands in another.

This latter property was utilised by Prof. Langevin of Paris to produce high-frequency sound vibrations by applying alternating electric potentials to electrodes in contact with a quartz plate. The plate vibrates with its maximum amplitude when the frequency of the electrical alternations coincides with a natural frequency of mechanical vibration of the quartz; in other words, when resonance is obtained.

For our experiments we use a quartz crystal cut in the form of a circular disc more than 7 centimetres in diameter and nearly 5 millimetres thick. This is clamped with one face in contact with a massive lead electrode and immersed in transformer oil contained in a small glass tank (Fig. 1). The second electrode, which is made of light copper foil, rests in contact with the other face, and both electrodes are connected to a powerful (3 kilowatt) valve-oscillator, executing half a million vibrations a second, or more. The use of the oil permits the application of very high voltages to the crystal, and also makes it easy to subject small objects to the influence of the very intense vibrations.

EXPERIMENTS WITH A HORIZONTAL BEAM OF SOUND.

Following Prof. R. W. Boyle, the production of *stationary waves* in the oil can be rendered visible by the striæ formed in coke dust scattered on a horizontal opal-glass plate placed in the sound beam. The distance between successive striæ, that is, half a wave-length of the sound in oil, is here between 1 mm. and 2 mm. This wave-length is so short in comparison with the dimensions of the crystal and other objects in the tank that these waves exhibit the directional properties ordinarily associated with light waves. Thus, by using plane and curved reflectors, the well-known laws of reflection are verified. In the same way refraction of sound waves by prisms and lenses can be demonstrated. Fig. 2 shows that sound waves travelling through pentane, and falling on a parallel layer of transformer oil, are transmitted if the angle of incidence is less than a certain value (critical angle), but totally reflected if it exceeds this value (total internal reflection). In fact, most objective optical phenomena, except polarisation, can also be faithfully paralleled by these means.

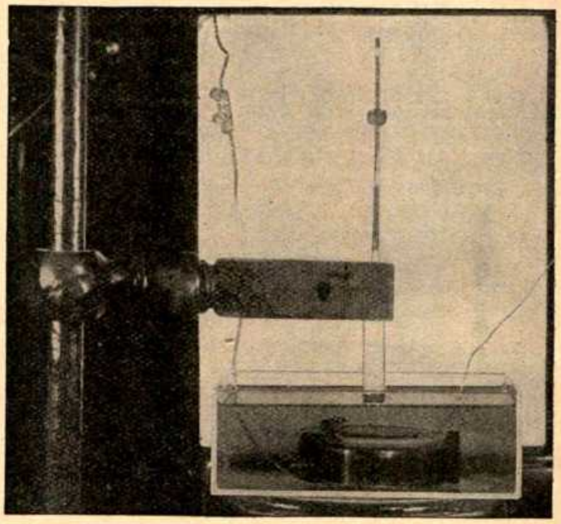


FIG. 1.—Arrangement of quartz crystal and electrodes in oil bath when projecting a vertical beam of sound.

Another application of the coke-dust method of showing stationary sound waves is to the study of architectural acoustics. Fig. 3 shows the 'whispering gallery' effect in a model of the lecture theatre of the Royal Institution, using ultrasonic vibrations instead of audible sound. The clinging of the waves to the circular wall is very marked.

The *pressure of radiation* to which an obstacle is subjected when sound waves fall upon it is shown by the rotation of the vane of a torsion pendulum placed in the horizontal ultrasonic beam. This affords a convenient method of estimating the intensity of the sound, which can be used for measuring the acoustic reflection and transmission coefficients of different materials.

---

* From a Friday Evening Discourse delivered at the Royal Institution on Feb. 13.

EXPERIMENTS WITH THE ULTRASONIC BEAM DIRECTED TOWARDS THE SURFACE OF A LIQUID.

The properties of ultrasonic waves described above were predicted from theoretical considerations before they were experimentally demonstrated by Langevin, Boyle, and others. Remarkable and hitherto quite unforeseen effects can, however, also be produced by ultrasonic vibrations when these are of great intensity and very high frequency.

With the crystal arranged as shown in Fig. 1, the ultrasonic beam is confined mainly to the column of liquid between the upper crystal face and the surface of the oil. Prof. R. W. Wood and Mr. Loomis have shown that in these circumstances the great concentration of energy causes the amplitude of vibration of the disturbed particles of liquid greatly to exceed the amplitude of vibration of the crystal itself. At the same time the pressure of radiation produces on the surface a mound of oil, several centimetres or even inches in height, which erupts droplets like a miniature fountain. On plunging vessels of appropriate form into this mound of oil, vibrations of great intensity may be communicated to the walls of the vessels, or through the walls to liquids contained in them. If a test-tube containing water is partially immersed in the oil, bubbles of dissolved gas are usually liberated in it (Fig. 4). These behave in a peculiar manner. For moderate intensities of vibration the bubbles form slowly and remain practically stationary at the nodes of the waves formed in the water. As the bubbles grow in size they oscillate and tend to rise to the surface in an irregular zigzag manner as if they were going up a staircase. For still greater intensities we have found that no visible gas bubbles can either exist or be formed. The density of the gas being much less than that of the liquid, the bubbles formed at low intensities must experience the same forces and therefore have greater amplitudes of vibration than the particles of liquid they displace. The result is that at high intensities they are deformed and shattered and so dispersed through the liquid as to become and remain effectively in solution.

Cavitation can be produced in liquids such as pentane or benzene, by using a U-tube closed at one end, the closed limb being filled with the liquid, and placed in the mound of oil above the vibrating crystal. The bubbles of vapour formed in the interior of the liquid and collected in the closed limb can be again condensed into liquid by raising the air pressure on the open limb. Using now an inverted U-tube or ∩-tube, which is completely sealed up and contains liquid in one limb only, we observe the rapid vaporisation of liquid in the agitated

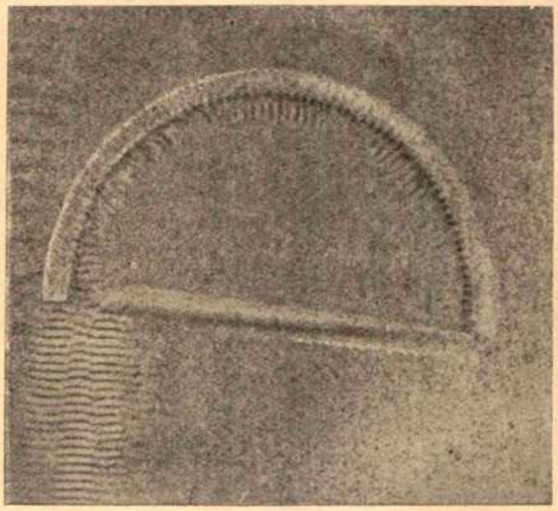

FIG. 3.—Model of lecture theatre of Royal Institution, showing 'whispering gallery' effect, illustrated by stationary waves of ultrasonic 'sound' of 2 mm. wave-length. Notice how the waves hug the wall.

limb and its deposition as liquid in the previously empty limb. This might appropriately be called *acoustic distillation*.

On substituting for the inverted U-tube a similar tube which contains a little dry lycopodium powder but is otherwise highly evacuated, an astonishing result is obtained. The powder sometimes moves in this case *towards* the limb which is subjected to the more intense vibration. This last effect is one of a number of phenomena due to the transverse vibrations of various types set up in the walls of the vessel itself. Another of these effects is the formation of ripples in the oil splashed on the tube and the repulsion of the oil drops away from the source of disturbance.

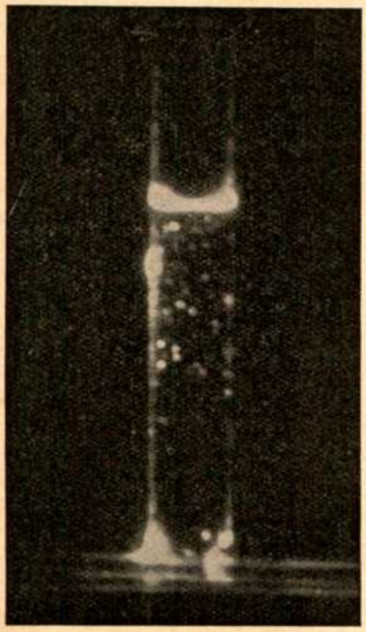

Fig. 4.—Expulsion from water of dissolved air as bubbles.

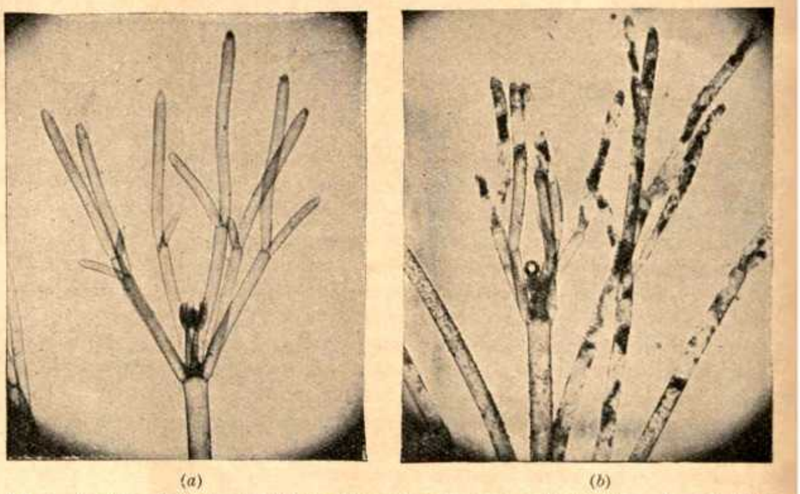
The most striking thing, however, about the oil drops is their behaviour at a constriction, or at the narrower parts of a tube such as is shown in Fig. 1. High inputs of ultrasonic energy cause intense local heating at such places, and the oil is thrown off as spray and jets of vapour as from diminutive geysers. If the tube is drawn off into a fine fibre and firmly grasped between the fingers, a severe burn is experienced. In addition to the calorific effects produced in the walls of various containers, the absorption of sound energy which occurs in their contents causes appreciable rises of temperature in them also. Amongst other effects which we can produce by our installation, we may cite the acceleration of certain chemical reactions, the flocculation of suspended matter, and the emulsification of oil and water, etc.

Most of the effects obtainable with the ultrasonic beam directed towards the surface of a liquid were discovered by Wood and Loomis in the United States. Acoustic distillation, the anomalous movement of lycopodium powder, and the non-liberation of bubbles from water with very high intensities are, we believe, described now for the first time.

Biological Effects of Ultrasonics.

Some fifteen years ago, while carrying out experiments at sea, Langevin and his co-workers observed that fish which swam into a beam of ultrasonic waves were disabled or killed. During the past few years I have been able to investigate this phenomenon. Quite independently, Wood and Loomis covered much the same ground. Let us notice first what happens to an object the dimensions of which are large compared with the wavelength of the sound waves which irradiate it. One result can be seen from Fig. 5. These are reproductions of photomicrographs of a freshwater plant —*Nitella*. The irradiated specimen shows how certain regions in a cell are denuded of their chloroplasts, which are then piled up in other spots. A gentler irradiation merely causes the streaming of the protoplasm to cease either temporarily or permanently according to the duration of exposure. The mechanical action which has taken place here can be understood when it is realised what occurs in the water in which the plant is immersed. Although the excursion of a disturbed particle during a single vibration is only equal to a few wavelengths of light, these vibrations, occurring at the rate of nearly a million times a second, cause the maximum velocity of the particle to be very high; its maximum acceleration may become as great as 10 km. per sec. per sec. We have, in effect, a *micro ultra-centrifuge*, which subjects specimens to very intense though highly localised forces.



(*a*) (*b*)

Fig. 5.—(*a*) Normal *Nitella*; (*b*) *Nitella* after exposure to ultrasonic vibrations. ($n = 750{,}000$.)

This explanation accounts quite satisfactorily for certain other effects we have obtained, such as the breakdown of the red blood-corpuscle and the disruption of Planaria and similar small living organisms. The same explanation may possibly account for the decreased response to stimulation of an irradiated muscle-nerve preparation and the arrest or retardation of the beating of the isolated frog's heart and embryonic heart of a chick.

Further explanation is required to account for the action on bacteria and viruses—bodies which are of microscopic and ultra-microscopic dimensions. We have found that the agglutinating power of certain streptococci is increased after irradiation, but the virulence of a strain of pneumococcus was unchanged or changed in an indefinite manner. (Preliminary experiments with bacteriophage have given a negative result.)

Positive effects have been obtained with one virus. The accompanying table shows the effect of ultrasonic vibrations in increasing the potency of the virus of vaccinia. Through the kindness of Dr. Mervyn Gordon, the irradiated and control lymphs in various dilutions were used to vaccinate the skin of a rabbit. The 'takes' were recorded after the requisite period of time had elapsed for the characteristic lesions to be produced. Two series of experiments were carried out, the lymph in the first case being given only one-fifth of the exposure given in the second case. It will be noticed that the result is the same in both cases. Presumably the effect of the exposure was merely to disengage inert foreign material from the virus so that the latter could exhibit its intrinsic potency.

EFFECT OF ULTRASONIC VIBRATIONS ON VACCINIA VIRUS.
(Frequency 700,000.)

Dilution.	*1st Expt.*	*2nd Expt.*	*Control.*
1/1	+	+	+
1/10	+	+	+
1/50	+	+	+
1/100	+	+	+
1/500	+	+	−
1/1000	+	+	−
1/2000	−	−	−

We have seen that fish may be killed by means of inaudible sound waves. With so many effects occurring simultaneously—the breaking up of blood corpuscles; liberation of dissolved gases; paralysis of muscle and nerve; localised mechanical action and heat production—this should no longer surprise us. In conclusion, it may be added that ultrasonic radiation is not a menace to human life. The vibrations are of necessity produced in a liquid because at these high frequencies the waves are so rapidly attenuated in air that their propagation through it is practically impossible.

Obituary.

DR. THOS. A. EDISON.

BY the death at Llewellyn Park, West Orange, New Jersey, on Oct. 18, of Thomas Alva Edison, America has lost one of its most famous men, and one whose name, like those of his countrymen Fulton, Whitney, Colt, Morse, Bell, Maxim, Westinghouse, and the Wright brothers, will always be remembered as that of a great inventor. When a youth, Edison bought a set of Faraday's works, and he afterwards said, "I think I must have tried everything in those books." It was in this direction his great strength lay; for, gifted with a vivid imagination and a quick and active mind, he possessed a remarkable willingness to put everything to the test, and to seek in any and every direction for a solution to the problem of the moment.

Edison came of Dutch and Scotch descent, and was born at Milan, Ohio, on Feb. 11, 1847. It was apparently from his mother that he inherited his intense mental activity, while from his father's side came his exceptional physique and powers of endurance. His great-grandfather lived to the age of a hundred and four years, his grandfather to a hundred and two, and his father and several uncles to more than ninety years of age. The romantic story of his early life has many parallels in American biography. Owing nothing to schools or masters, he was his own instructor and the founder of his own fortunes. As a train boy of fifteen years of age he printed a small newspaper, the first ever produced on a train in motion; at sixteen years he was a telegraph operator; at nineteen he took out his first patent; at twenty-two he was working for a telegraph company at 300 dollars a month, and soon afterwards was able to sell his improvements in 'stock tickers' for 40,000 dollars, and in 1876 to open his laboratory at Menlo Park, Newark, New Jersey.

The record of the work of Edison and his assistants during the next twenty years at Menlo Park and at West Orange, to which he removed in 1887, probably has no parallel in the history of invention, and it is no wonder he became popularly known as the 'Wizard of Menlo Park'. It has been said of him that "he could always be counted upon to play his part in the mechanical evolution of new inventive arts", but his part often became the principal one. In telegraphy he will be remembered for the invention in 1872 of the type printing receiver and his subsequent work on quadruplex telegraphy, while to telephony he contributed the important invention of the carbon transmitter. Bell invented the telephone in 1876, Hughes the microphone in 1878, and Edison the carbon transmitter in 1877. To that year also belongs his outstanding invention of the phonograph.

Two years later Edison successfully solved the problem of "the subdivision of the electric light" by the invention of his incandescent lamp, his work in this direction being contemporary with that of Maxim, Lane Fox, and Swan. His improvements in the dynamo, made about the same time, gave him a place beside Gramme, Siemens, Crompton, Brush, and Hopkinson; while the first central power stations in both the Old World and the New World, the former in Holborn Viaduct, London, and the latter in Pearl Street, New York, were the direct outcome of his many inventions. Both these stations began operations in 1882.

In Menlo Park, in 1880, Edison made experiments with electric traction, while he afterwards contributed to the advancement of photography and cinematography. One fruitful observation he made in 1883—the Edison effect—he left for others to utilise; and from this, through the work of Sir Ambrose Fleming, came the thermionic valve. The work of an inventor responsible for more than a thousand patents cannot be adequately dealt with in an obituary notice, but, in conclusion, mention may be made of his nickel and iron storage cell patented in 1900 and improved in subsequent years.

Many biographies of Edison have been written and many writers have put forward extravagant claims on his behalf. But he himself stood in need of no such panegyrists. His works speak for themselves, and the *Times* remarks that though his older friends and staff have passed away, "those who survive him retain an abiding impression of him as a great man, and a singularly delightful personality, devoid of egotism, inspiring enthusiasm and exceedingly human, as all who share his love of children must be".

For fifty years Edison's name has been a household word, and it is nearly forty years since it was included in the list of recipients of the Albert Medal of the Royal Society of Arts, where it is found beside those of Faraday, Wheatstone, Bell, Hughes, Kelvin, Swan, Parsons, Fleming, and Marconi. It is among such as these he rightly takes his place.

Dr. C. A. Keane.

Dr. Charles Alexander Keane, who died, at the age of sixty-seven years, on Sept. 18, had been identified for the last thirty years with the development of technical education in London. After studying at Manchester under Roscoe and at Erlangen under Otto Fischer, he served as lecturer and demonstrator in chemistry at Liverpool for fifteen years before coming to London to take up the post of first principal of the newly established Sir John Cass Technical Institute. This Institute was founded out of the increased revenues of the trust established by Sir John Cass (1661–1718) for the maintenance of a Foundation School for the children of the Ward of Portsoken. Appointed in 1901, almost a year before the opening of the new building in Jewry Street—now, in eloquent testimony of the success of his administration, undergoing extensive enlargement—Keane at once gained the confidence of the governors, and was able to determine from the very beginning the lines on which the Institute should develop. As soon as possible another building was provided for Sir John Cass's Day School, and all elementary teaching was given up in favour of more advanced work. Two chief principles were adopted: first, the encouragement of research among the teachers and senior students, and, secondly, close association with the industries of the district. In both these respects the Sir John Cass Institute has fulfilled the wishes of its promoters; a long list of original researches has been published from its laboratories, while its industrial classes, each controlled by a consultative committee representing its special subject, are a characteristic and flourishing feature of its work.

Keane contributed a number of papers on organic chemistry to the *Journal of the Chemical Society*, but his chief interests lay in applied chemistry, and he did pioneer work on electrolytic methods of analysis and the analysis of gases. He wrote a book on "Modern Organic Chemistry", intended for readers with no special chemical training, and edited the English edition of Lunge's "Technical Methods of Chemical Analysis", which was completed in 1914 and was followed by a revised edition on which he was engaged almost to the time of his death. He was an active member of the various societies associated with chemistry, and acted as chairman of the London Section of the Society of Chemical Industry in 1917–19, a position in which his sound common sense and business acumen proved of great value.

Keane retired from his post at the Cass in 1926 after a period of ill-health culminating in a serious operation, and spent the remaining five years of his life at his country home near Canterbury, actively engaged in local affairs. A man of wide interests and culture, and a charming companion, his loss will be severely felt.

A. H.

Prof. Fritz Foerster.

We regret to record the death on Sept. 14 of Prof. Fritz Foerster, Director of the Laboratory of Inorganic Chemistry of the Technische Hochschule, Dresden, and we are indebted to the *Chemiker-Zeitung* for Oct. 7 for details of his career.

Born in 1866 at Grünberg in Silesia, Foerster proceeded in due course to the University of Berlin, where he studied under A. W. von Hofmann. After graduation he became assistant to Mylius at the Physikalisch-Technische Reichsanstalt, and in 1894 he joined the staff of the Technische Hochschule in Charlottenburg, but in the following year he accepted a post as lecturer under Walter Hempel at the Hochschule in Dresden, where in 1900 he was appointed to the new chair of electrochemistry and physical chemistry. In 1905 a new laboratory of electrochemistry was established under his direction, and in 1912, on the retirement of Hempel, Foerster was elected to the chair of inorganic and technical chemistry. After the War he applied himself to the task of rebuilding the Chemical Institute, which was ready for occupation in 1925.

Foerster's experimental work lay chiefly in the field of electrochemistry, the bulk of his original papers being published in the *Zeitschrift für Elektrochemie*. The problems which he investigated cover a very wide field, and include the electrolysis of alkali chlorides and the salts of the halogen oxy-acids, as well as electro-analytical methods and technical applications. During the last twelve years he was particularly concerned with an investigation of the chemistry of the oxy-acids of sulphur and the electrolytic reduction of compounds of polyvalent metals. His well-known handbook "Elektrochemie wässeriger Lösungen" (1905) is recognised as a standard work on the subject. In 1923 he began to remodel the whole work, and the first volume was approaching completion at the time of his death.

News and Views.

THE Pedler Lecture of the British Science Guild was delivered to the University of Durham Philosophical Society at Armstrong College on Oct. 21 by Prof. J. Irvine Masson, who took as his subject "Problems in the National Teaching of Science". Reviewing, on a national scale, education in pure science, as it is carried on at our universities and in schools, Dr. Masson asked if the pendulum has overswung. Are we teaching too much science or teaching science too much ? To those who are going to be lifelong scientific workers we have to, and do, give an intensive training ; but every science is now swelling so quickly that it can no longer be confined within the three-year limit of the undergraduate course. Two more years are needed and are actually expected of a young man before he is eligible for a first post as a practising scientific worker. This needs universal recognition. Prof. Masson is of opinion that we are trying to teach too much and too specially to those who are not going to be professional scientific workers. The figures for the whole country show a great preponderance of 'honours' over 'pass' students, and a great many of these honours specialists do not go on with further training in their science, but turn to school-teaching, besides other occupations.

TEACHERS carry into schools the same exclusive specialisation, and a vicious circle is created, which is helped by the higher salaries paid to school-teachers who are honours graduates. Prof. Masson thinks that if this were altered, and the universities reformed their pass-degree courses, we should get much better balanced teaching in schools ; and the whole series of educational sieves through which our young people pass (or are forced) would work naturally. In the schools, especially the secondary schools, exaggerated science teaching is given on a very large scale from absurdly youthful ages, while other subjects (for example, German) are neglected. These things are as bad for the future scientific worker as they are for all other students. They can be cured by the reforms already mentioned, coupled with a change in the functions of the school certificate. In an appendix to the printed lecture, these arguments are supported by a statistical survey, which shows the trend during recent years in the choice of pursuits at the universities and schools of the realm.

DR. F. C. BENHAM, in a report on "Fluctuations in Employment in Great Britain", prepared for the recent meeting of the World Economic Congress in Amsterdam, stated that the general standard of living in Great Britain is now probably higher than before the War. A recent inquiry by the Ministry of Labour showed that weekly full-time rates of wages, for those classes of adult workpeople for which information is available, averaged between 70 and 74 per cent in December 1930 above the level of August 1914. Weekly earnings of which the wage index takes no account have increased still more, while there have been also considerable reductions in normal weekly working hours, which in effect mean that hourly rates of wages are between 90 and 100 per cent higher. The cost of living, however, is less than 60 per cent higher. Thus 'real' weekly wages are appreciably greater and hours of work are less. At the same time, the transference of income, through the machinery of public finance, from the relatively rich to the relatively poor is much greater. Yet against all this must be set the large numbers of unemployed, which tend to bring down average 'real' yearly earnings. During the past twenty years, methods of production have improved, technical efficiency has increased, and the productive capacity of the world appears greater than ever before. Undoubtedly a marked increase of economic welfare would take place if only the vast number of unemployed could be absorbed into industry. The problem, however, is a world problem, and will only be solved by intelligent co-operation between the various nations.

THE Annual Report of the Director of the Meteorological Office for the year ending March 31, 1931, which has just been published by H.M. Stationery Office, describes the principal activities of our national meteorological institution's seventy-sixth year. It records a steady all-round increase in the application of theoretical meteorology to the practical affairs of everyday life, shown by an always growing number of applications for expert advice in matters connected with climate and weather, in each of the various sections into which the Office is divided. We learn that in addition to activities of this kind, much of the time of the staff was devoted to carrying out decisions made at three important conferences held in 1929, namely, the International Conference on Safety of Life at Sea, the Conference of Empire Meteorologists, and the International Conference of Directors of Meteorological Services. Among the changes involved are those relating to the interchange of weather reports by wireless on land and at sea. Owing to the increasing amount of interference between the wireless issues on land of different countries consequent on expansion of programmes arising from the needs of growing aviation services, it was found necessary to arrange for fewer, but more comprehensive, wireless messages. These are issued by powerful stations in the United States, Great Britain, France, Germany, and Russia. The exchange of wireless weather reports at sea has been comparatively little affected. The increasing responsibilities of official meteorology have been met to a large extent by frequent revision of methods of work with the object of making the most efficient use possible of the available establishment, but the creation of a few new posts was found to be unavoidable, and among these may be mentioned the appointment of an officer to take charge of special investigations into problems of atmospheric visibility connected with aviation, naval operations, and lighthouses.

AT a recent meeting held at Locarno, the International Meteorological Committee agreed upon the programme of meteorological, magnetic, and electrical research to be undertaken in the Arctic regions during the winter 1932–33, in accordance with the decision to organise a second 'International Polar Year' on the fiftieth anniversary of the first undertaking of this character. The scheme involves the setting up of a circumpolar chain of temporary observatories, equipped with special apparatus for the work to be done. In view of the long Arctic coast-line in Russia and Siberia, it is obvious that the co-operation of the Russian Government is particularly desirable; it is satisfactory to learn, therefore, not only that such co-operation will be forthcoming, but also that the Russian contribution is likely to be the largest made by any one country. It is unfortunate that the organisation of an enterprise such as this, which involves financial expenditure without immediate economic return, should coincide with the 'economic blizzard'; but although this has prevented some governments from assisting financially, private help has generally resulted in the necessary funds being available, and on the whole the scheme promises well. Of the many great improvements in equipment that the past fifty years have made possible, those due to the development of wireless telegraphy may be noted especially. There is a possibility that the problem of obtaining observations of pressure, temperature, and humidity at high levels in the atmosphere, in regions where the ordinary instruments sent up in registering balloons are not likely to be recovered, may be solved by an apparatus which automatically emits wireless signals when the quantities to be measured reach certain predetermined values.

THE wet nature of the recent summer in England considerably increases interest in the results of the combined harvester-thresher machine trials. Demonstrations have been given in different parts of the country, and information from the Institute of Agricultural Engineering at Oxford regarding the performances of the machines is given in a recent statement issued by the Ministry of Agriculture. Eleven machines in all were used, one of which for the first time is owned by a contractor, while nine belong to private farmers. About 1500 acres of cereals was cut, most of which was barley, the superiority of the combine over ordinary methods of harvesting being particularly marked with this crop. Good malting samples, fetching prices of 45*s*.–50*s*. per quarter, have been obtained where, owing to the wet season, the crop would have been seriously damaged if exposed in stooks in the normal way. The additional use of a drying machine is not essential, but as it allows of starting harvesting operations much sooner after rain, the advantages may be considerable. The best day's work was done by a caterpillar combine used by Mr. G. H. Nevile of Wellingore, Lincs, and consisted of cutting 14 acres of oats, yielding altogether 144 sacks. The question of straw remains a problem, as the present type of combine, designed to suit American conditions, is unable to deal with a crop more than 3 ft. in length. Messrs. Clayton and Shuttleworth have, however, now produced a British machine which seems able to overcome this difficulty. As an alternative, in districts where the straw is very long and of sufficient value, a binder may be used in conjunction with the harvester-thresher, or shorter straw can be gathered with a hay-loader and put in a rick or baled in the field. Apart from these minor difficulties, it is evident from this year's experience that combine machines are a thoroughly practical proposition for use in England, and that they are of particular benefit to the barley grower in wet seasons.

A MEETING of the administrative council of the Empire Cotton Growing Corporation was held in Manchester on Oct. 21, and the Right Hon. the Earl of Derby, president, presented the quarterly Report of the Executive Committee. One important point in the Report is that the Committee has decided to recommend that each experimental station should only be required to produce a full report every third year. Thus each annual volume would contain four full reports, while the remaining eight stations would produce summaries only of the work of the last season. The stations would thus produce their full reports in rotation. The Committee recommends that stations from which summaries only are required should, nevertheless, take care to include in those summaries, or in a separate note if desired, any observations or results that may be of immediate use to co-workers. Lord Derby remarked that the finances of the Imperial College of Tropical Agriculture are a source of anxiety to the governing body of the Empire Cotton Growing Corporation, owing to a reduction made by the Empire Marketing Board in the grant and the possibility of a diminution in the amount of the sums receivable from overseas contributors. The Corporation takes the greatest interest in the work of the College, which has led to great improvement in the standard of the agricultural officers in the Colonial service. Any curtailment of the activities of the College or impairment of its efficiency would be a real calamity.

IN the Report are references to administrative changes and work at the various experimental stations. Before the Research Committee, Dr. Harland reported on the work of the Genetics Department, and gave a résumé of what had been accomplished during the first five years since the Research Station at Trinidad was established. The climate has provided no obstacle to progress which it was not possible to overcome, but it has been found necessary to adapt the technique of the work to meet difficulties that have arisen. Various insect pests have, however, proved rather a limiting factor, and for this reason Dr. Harland is extremely glad that the Corporation has reopened the Experiment Station in St. Vincent, where the obstacles to cotton growing are less formidable. At the same meeting, Sir James Currie, Director of the Corporation, reported certain matters which had arisen since the Report was drafted. In the Sudan this season, the crop has so far suffered much less from disease than last year, and it is hoped that satisfactory yields will be obtained. In the rainfall districts, it is interesting to note that the variety tests with American cotton have indicated that the Corporation's U.4 strain from Barberton has yielded better than all other varieties, both in Mongalla and in the Nuba Mountains. Its quality, moreover, appears to be satisfactory.

CAPT. J. M. DONALDSON in his presidential address to the Institution of Electrical Engineers on Oct. 22 dealt mainly with the work being done by the large electric power companies, which are out of touch with the national network of power lines now being rapidly erected round Great Britain. In London, the London Power Company has been carrying out in a quiet and unostentatious manner a remarkable work of unification and consolidation. The company controls and has linked up the power stations at Deptford, Bow, Grove Road, and Willesden, and the large Battersea station now being erected will form part of the group. Last year its output was 819 millions of units, and the maximum demand at any one time was 283,400 kilowatts. Another group consists of the County of London and City of London companies. The main power station of this group is at Barking, where plant producing 240,000 kilowatts is installed. At the present time this is the largest power station in Great Britain. A further extension of 150,000 kilowatts has been authorised. A large fraction of the output is sold outside London. The possibility of linking up the large private companies was considered, but it is very doubtful if the companies would have been willing to agree to this some years ago when the national scheme was first introduced. The dwellers in the country are well aware of the low prices of electricity which are charged in many towns. They naturally think, therefore, that the much higher price they have to pay is inequitable. This is not the case, for the cost of supplying electricity in the rural areas depends more on the density of the population than on other considerations. In technical language, it depends on the revenue per mile of the supply main.

IN a paper on radio research in the British Empire read by R. A. Watson Watt and O. F. Brown to the British Association on Sept. 28, an account was given of the collaboration between the home and dominion boards of radio research. The study of atmospherics has proved that in order to make real advances in our knowledge, the observing network must be spread over the whole surface of the globe. This problem is of vital importance to the radio engineer. Attenuation and fading may reduce the received intensities, but it is easy to compensate for them by gain control at the receiver. With atmospherics, however, the compensation can only be usefully carried to the point at which the noise level due to atmospherics, to artificially generated disturbance, or to internal set noise becomes comparable with the signal. Set noise can be mitigated, artificial disturbance avoided, but an irreducible minimum of atmospheric disturbance must be accepted along with the desired signal. The Radio Research Board, therefore, does not deal with the elimination of atmospherics but with their nature and origin. On the radio communications side the Board has made its contribution to the demonstration of the limits of atmospheric mitigation. On the geophysical side it is still exploring the possibilities of utilising atmospheric observations in practical meteorology. It is now proved that the interesting phenomena of reflection from the Kennelly-Heaviside layer are related to the terrestrial magnetic field. It will therefore be of great interest to compare the data obtained from observations made in the northern and southern hemispheres.

HIS MAJESTY THE KING has graciously placed on loan in the Department of Botany of the British Museum (Natural History) a collection of plants presented to him by the University of Buenos Aires. The collection contains 302 named plants, which are of great scientific and historical interest, as they were gathered during the Delimitation Expedition (1902–3) under Sir Thomas H. Holdich, the Royal delegate appointed by Edward VII. on the request of the presidents of Argentina and Chile to determine the Patagonian Argentine-Chile frontier. The University of Buenos Aires charged certain members attached to the Arbitration Commission with the making of a systematic botanical survey of the difficult areas. The dried specimens were divided into three lots—one was retained at Buenos Aires, another was presented to the Valparaiso Museum, and the third was preserved until an opportunity arose of delivering " with the homage of Argentina to His Britannic Majesty this historical material collected in the fulfilment of the judgment which re-established peace and harmony between the sister nations." The collection was entrusted to Lord Moynihan on his recent visit to Buenos Aires. It is accompanied by two volumes of collotype reproductions, one containing unpublished letters of A. von Humboldt, the other the botanical journal of his pupil, A. J. A. Bonpland. The Department of Botany has also been presented with a collection of 446 Angolan plants by Mr. J. Gossweiler, well known for his botanical exploration in Angola. Mr. J. J. Joicey has added to his previous benefactions to the Department of Entomology of the Museum by presenting the whole of his Indo-Australian Noctuidæ, the Geometridæ other than the African species, the Ægeriidæ (Clearwings), and the types of many species belonging to several other families. Recent acquisitions by the Department of Mineralogy include one of the many masses of meteoric iron found in June 1931 around the large meteorite craters near the Henbury cattle station, Finke River Central Australia, presented by Prof. Kerr Grant.

IN *Engineering* of Oct. 16 is an illustrated account, by Mr. A. E. Williams, of the coco-nut oil industry, with descriptions of the machinery in use. There are approximately 7,000,000 acres of coco-nut palms under cultivation, of which area more than one-half is in the British Empire. The chief botanical specimen cultivated is *Cocos nucifera.* Some seven or eight years elapse between the planting of the palms and the time they bear fruit, while the fruiting period is from sixty to seventy years. Each tree yields annually from eighty to ninety nuts. Of the nuts, the dried kernel, called copra, is used for its oil, the husk can be spun into coarse yarn, while the shell is used for fuel or for the manufacture of charcoal. The essential parts of a modern plant for obtaining coco-nut oil include drying furnaces for the copra, grinding mills for reducing the copra to meal, and hydraulic presses for expelling the oil from the meal. Before being pressed, the copra meal is heated in steam-heated kettles, and by this means it is possible to reduce the oil content from 70 to 6 per cent. The residual meal is valued as a cattle foodstuff. Coco-nut oil represents about twelve per cent of the total oils and fats used in soap manufacture in Great Britain and about twenty per cent in America, while it represents about fifty per cent of the total margarine made in America and about thirty-five per cent made in Great Britain. It is also used in chocolate and toffee manufacture.

THE Government of India has authorised the issue by the Zoological Survey of India of a third serial, additional to the *Records of the Indian Museum* and the *Memoirs of the Indian Museum.* Since the appointment of Dr. B. S. Guha as anthropologist to the Zoological Survey, provisionally for a period of two years in 1927 and permanently as from 1929, a considerable amount of research work in anthropology has been and is being carried out; while it is hoped that from time to time reports will be available for publication dealing with research on the population, both past and present, of India. Up to the present the *Memoirs* and *Records* have dealt solely with zoological subjects, with one exception, a paper by the late Dr. Nelson Annandale. In order to avoid a change in the character of these publications, it has been decided to inaugurate a new series of *Anthropological Bulletins,* with the first of which, a report on the human relics recovered by the Naga Hills (Burma) Expedition, we deal elsewhere (p. 762).

THE Report of the Irish Radium Committee for 1930 in *Sci. Proc. Roy. Dublin Soc.*, vol. 20 (N.S.), No. 10, p. 99 (also separate issue), states that the generosity of members of the Royal Dublin Society and of the general public enabled an additional amount of 496 mgm. of radium to be purchased, bringing the total quantity available up to 907 mgm. From the several medical reports included, it is evident that rodent ulcers and skin cancers react most favourably to radium treatment, with a cure in some 80-90 per cent of the cases. Cancer of the tongue, when not too extensive, and of the uterine cervix, yield 40-60 per cent of cures. Cancers of the breast, rectum, and other regions are seldom cured, though now and then a striking result is obtained. It has to be remembered, however, that most of these cases are too advanced for successful operation. Certain non-malignant conditions, such as uterine hæmorrhage, also react favourably to radium treatment.

IN NATURE for Sept. 12, p. 440, reference was made to the obscurity that prevails as regards the function of the forceps of the common earwig. We have since received letters from Mr. M. H. Lapidge, of Hampton Wick, and Dr. van der Sleen, of Haarlem, concerning this subject. Both correspondents mention having personally observed these insects to use their forceps in manipulating their wings. Mr. Lapidge states that he has several times seen earwigs use their forceps to fold up their wings beneath the tegmina. Dr. van der Sleen, on the other hand, remarks that he has observed these insects using their forceps for opening their wings. While it seems certain that one of the functions of the forceps is in connexion with the manipulation of delicate and complexly folded wings, their main use can scarcely be regarded as having been definitely settled.

THE monthly journal *Mikrokosmos* with the October issue commences its twenty-fifth annual volume. *Mikrokosmos* aims at extending knowledge of microscopy, and publishes papers on current topics and progress in all branches of microscopy. In the present number, Prof. W. J. Schmidt reviews the progress of histology during the last twenty-five years, Dr. H. Dohrer describes the infection of flies with the fungus *Empusa muscæ*, Dr. Karl Berger writes on the early 'flea' magnifiers, and Dr. G. Venzmer describes what tropical medicine owes to microscopy. Other articles deal with microscopy in schools and with laboratory technique. The journal is well produced on good paper, so that photomicrographs, of which there are several, are adequately reproduced. *Mikrokosmos* is edited by Dr. G. Stehli and published by Franckh'sche Verlagshandlung, Stuttgart, at 2·40 gold marks a quarter.

THE Council of the Institution of Chemical Engineers has appointed Mr. H. W. Cremer to be honorary secretary of the Institution in succession to the late Prof. J. W. Hinchley.

ON the occasion of the opening of the new laboratory of physical chemistry at the University of Freiburg im Breisgau on Oct. 30, honorary degrees were conferred on Lord Rutherford, Prof. Manne Siegbahn, professor of general physics in the University of Uppsala, and Prof. V. M. Goldschmidt, of Göttingen.

THE Ministry of Agriculture and Fisheries has appointed Mr. J. S. L. Gilmour, Curator of the University Herbarium and Museum, Botany School, Cambridge, to be Assistant Director of the Royal Botanic Gardens, Kew. Mr. Gilmour was educated at Uppingham School and Clare College, Cambridge, where he took the Natural Sciences Tripos, Part I. and Part II., Botany.

IT is announced in *Science* for Oct. 9 that Prof. Stephen H. Langdon, professor of Assyriology at the University of Oxford, and Dr. Ludwig Diels, Director of the Botanical Garden and Museum of Berlin-Dahlem, have been elected corresponding members of the Field Museum of Natural History, Chicago, by the board of trustees, in recognition of their eminent services to the museum.

A COURSE of twelve public lectures by Prof. Lancelot Hogben, research professor of social biology in the University of London, on "Genetic Principles in Medicine and Social Science", has been arranged by the London School of Economics and Political Science, Houghton Street, Aldwych, London, W.C.2. The first lecture will be given on Nov. 27, and the following eleven lectures on Fridays, at 5 P.M. Admission to the whole course is free and without ticket.

At the conversazione of the Belfast Naturalists' Field Club, which was held on Oct. 20 to mark the opening of the winter session, the Club medal was awarded to Mr. S. A. Bennett, formerly science master at Campbell College, for his scientific attainments and his work with the Club from 1908 until 1926. Mr. Bennett was on the Committee of the Club from 1913 until 1926, for three periods was secretary of the botanical section, and from 1919 until 1923 was joint editor of the *Proceedings*. In 1920 he was elected president of the Club, and held that office for two years. Mr. Bennett has contributed much to the knowledge of plant distribution in Northern Ireland, and has done valuable work in local geological and anthropological problems, especially on the recently discovered prehistoric site in County Antrim.

Prof. R. H. Dastur, of the Royal Institute of Science, Bombay, and his students arranged an interesting and instructive series of experiments illustrating the life processes and the life history of plants, on Sept. 30, at the C.J. Hall, Bombay. This date was arranged so that the exhibition should fall within the week of the centenary meeting of the British Association. Amongst the numerous exhibits were an apparatus for measuring the temperature of a leaf and an apparatus showing automatic records of the air diffusing into leaves through minute pores on their surface. The research work carried on in the Botany Department of the Royal Institute on the physiology of the rice plants has yielded results of practical value, and there were exhibits of living rice plants showing those results. The exhibition was followed by a lecture, illustrated with lantern slides, on "Plant Life on the Earth", by Prof. R. H. Dastur, when the vegetations of the different parts of the globe were illustrated on the screen, mostly in their natural colours.

The Worshipful Company of Woolmen gives a silver medal each session for theses relating to wool and the processing of wool. The nomination Committee this year has recommended that two medals be granted, namely, to Miss Emma Stott, of the University of Leeds, for a thesis entitled "A Contribution to the Theory of Milling", and to Mr. Kenneth Nicholls, of the Bradford Technical College, for a thesis entitled "Sulphur Content of Wools in Relation to Processing". The Committee has also recommended that certificates of merit be awarded for the following theses: Miss Evlyn Boyd (University of Edinburgh), on "Pigmentation of the Fleece of the Sheep"; Dr. R. O. Hall (University of Leeds), on "The Ventilating Properties of Textile Materials and Fabrics"; Mr. Arthur Johnson (University of Leeds), on "The Influence of Cloth Structure on the Rate of the Milling of Fabrics"; Mr. M. Tempelhof (University of Leeds), on "Studies in the Regularity of Yarns and Slivers by a New Mechanical Tester"; Dr. A. E. Wilson (University of Leeds), on "Physico-chemical Properties of Wool"; and Mr. George Bancroft (Bradford Technical College), on "The Influence of Environment on Wool". These recommendations have now been approved by the Court of the Worshipful Company of Woolmen.

We have received from Messrs. Gallenkamp the new issue of their "Catalogue of Chemical and Industrial Laboratory Apparatus". This is a handsome volume of 1471 pages, fully illustrated, and covers the scientific equipment applicable to practically every branch of industry. In a large number of cases brief but adequate descriptions of the use of the apparatus are included, so that the catalogue is much more than a mere list of prices. It should, in fact, be most useful in the school, university, or technical laboratory. The apparatus includes physical, botanical, and general biological equipment, and there is a detailed list of chemicals. At the end of the catalogue there is a useful list of books on various branches of chemistry, biology, medicine, and industry. Messrs. Gallenkamp are to be congratulated on the completeness of their catalogue and on the production of a useful and instructive volume.

Applications are invited for the following appointments, on or before the dates mentioned:—A senior assistant in the Bacteriological Laboratory of the Public Health Department, Glasgow—The City Bacteriologist, 20 Cochrane Street, Glasgow, C.1 (Nov. 7). An assistant in electrical engineering at the Wolverhampton and Staffordshire Technical College—The Clerk to the Governors, Education Offices, North Street, Wolverhampton (Nov. 9). A secretary of the Institute of Physics and Editor of the "Journal of Scientific Instruments"—The President, Institute of Physics, 1 Lowther Gardens, S.W.7 (Nov. 20). Crystalline Vitamin D.

Four crystalline preparations of vitamin D have recently been described[1] having approximately equal antirachitic activities (20,000-25,000 International Units per milligram) and similar absorption spectra, but differing widely in their optical rotations. It follows either that there are several substances having antirachitic activity or that none of these preparations is pure, and that the varying optical rotation is due to the presence of one or more impurities.

When we described our own preparation, to which the name 'calciferol' was provisionally applied, we could not exclude the possibility that it contained a certain amount of an inactive impurity. We have since found that when the crystalline material is heated at 180°, an inactive substance of very high dextro-rotation, 'pyrocalciferol', is formed. Since calciferol was obtained by distillation, it seemed probable that it was contaminated with pyrocalciferol, which would account for its remarkably high dextro-rotation. Evidence of the existence of isomorphous mixtures was given, moreover, by the fact that different preparations on repeated recrystallisation retained constant but different optical rotations.

The preparation of crystalline esters, the 3 : 5-dinitrobenzoates, which was reported in a paper read by one of us (R. K. C.) at the meeting of Section B of the British Association on Sept. 25, made available a new method of determining the nature of our crystalline material. Evidence had been obtained of the separation of the ester into two components, and the hypothesis was put forward that the distilled product was a mixture, or perhaps a molecular compound, of a substance with a higher antirachitic activity than any product yet obtained, and pyrocalciferol. The provisional conclusions then advanced have now been confirmed. On the basis of the biological tests so far completed, it would appear that our original preparations contained 30-50 per cent of inactive material, the dominant impurity being pyrocalciferol. Nevertheless, we think it may be justifiable to retain the name 'calciferol' for the active main constituent.

The product obtained by the action of 3 : 5-dinitrobenzoyl chloride on the crystalline material in pyridine has been separated by fractional crystallisation into two esters, each of which has been repeatedly recrystallised. *Calciferyl* 3 : 5-*dinitrobenzoate*, lemon-coloured plates, m.p. 145°-147°, $[\alpha]_{5461}^{20} + 104°$ in acetone, $[\alpha]_{5461}^{20} + 68°$ in benzene, yields on hydrolysis *calciferol*, m.p. 114·5°-117°, $[\alpha]_{5461}^{20} + 119{\cdot}5°$, $[\alpha]_{D}^{20} + 105°$ in alcohol, $[\alpha]_{5461}^{20} + 99°$, $[\alpha]_{D}^{20} + 81°$ in acetone, antirachitic activity 40,000 International Units per mgm.; the solution in alcohol has an intense absorption band with a maximum of $\epsilon = 46{\cdot}0$ at 265 mμ. *Pyrocalciferyl* 3 : 5-*dinitrobenzoate*, orange-coloured prisms, m.p. 167·5°-169·5°, $[\alpha]_{5461}^{20} + 250°$ in benzene, yields *pyrocalciferol*, m.p. 92°-94°, $[\alpha]_{5461}^{20} + 608°$, $[\alpha]_{D}^{20} + 494°$ in alcohol, showing no antirachitic activity; the solution in alcohol has an absorption band with maxima of $\epsilon = 15{\cdot}7$ at 296 mμ, 27·1 at 284 mμ, and 26·1 at 274 mμ. Both calciferol and pyrocalciferol are shown by analysis to have the same empirical formula as ergosterol.

Prof. Windaus recently suggested that our crystalline material was a mixture of his vitamin D_1 with a substance of very high rotation;[2] but calciferol, as now separated from pyrocalciferol, is evidently not identical with vitamin D_1, since the latter has a lower antirachitic activity and absorption coefficient and a higher optical rotation. Calciferol, however, resembles closely, in such physical properties as have been described, the "vitamin D_2" (m.p. 114°-115°, $[\alpha]_D + 85°$ in acetone) which Windaus mentions in an addendum to his paper as having been more recently prepared by Linsert. By the courtesy of Prof. Windaus we have seen the proof of a forthcoming paper in which the absorption coefficient of vitamin D_2 at 265 *mμ* is given, and corresponds closely with that of calciferol. The identity of the two substances however, cannot be assumed unless further experiment should show that vitamin D_2, like calciferol, has a substantially higher antirachitic activity than vitamin D_1, and not approximately the same activity, as stated. The antirachitic activity of calciferol is the highest yet recorded in known units for any preparation. Identity of calciferol with the 'substance L' of Reerink and van Wijk seems to be excluded by the great instability, lower absorption, and lower antirachitic activity of their product.

The supposition that calciferol is a direct product of the irradiation of ergosterol has been confirmed by the preparation of the 3 : 5-dinitrobenzoate directly from the undistilled, crude irradiation product. The ester and the sterol thus obtained show complete identity of properties with those from the distilled product, and the yield is such that the greater part of the antirachitic activity of the crude resin can be accounted for by the calciferol actually separated as the ester.

We much regret that Dr. Bourdillon, the leader of our team, has been prevented by illness from taking a direct part in this stage of the work.

A New Type of Magnetic Birefringence.

It is well known that salts of cerium and other rare earths exhibit in aqueous solution a Faraday effect or magnetic gyration of light in the *opposite* sense to that shown by the great majority of fluids. The phenomenon has been explained by Ladenburg, Becquerel, and others as an effect connected with the paramagnetism of the ions and their orientation by the magnetic field. The study of magnetic gyration in paramagnetic substances generally therefore possesses great interest. Incidentally, also, the question arises if, as has been suggested by Ladenburg, the paramagnetic ions are orientated by the field, whether the solutions should not exhibit magnetic *birefringence* when observed in a direction transverse to the field. Investigations made on both these points have yielded very interesting results.

A magnetic birefringence of the kind suggested by the orientation theory is definitely shown by salts of cerium, praseodymium, erbium, and yttrium in aqueous solutions, when observed in strong magnetic fields. In every case, using light in the visible region of the spectrum, the birefringence is *negative*, that is, of the same sign as that exhibited by carbon disulphide; and appears to be proportional to the concentration of the solutions. Solutions of lanthanum and gadolinium, on the other hand, fail to exhibit the effect, though gadolinium is strongly paramagnetic. The effect in dilute solutions where it is observed is of the same order of magnitude as that exhibited by organic liquids of the aliphatic class.

So far, no investigation has been made of the variations of the effect with the wave-length of the light used or with the temperature. There appears, however, to be a significant parallelism between it and magnetic gyration in each of the substances studied. The fact that gadolinium salts exhibit neither a birefringence nor any marked magnetic gyration, though they are strongly paramagnetic, seems very significant. Evidently, the question whether the magnetic moment of the ions arises from orbital motion or spin of the electrons is all-important.

It may be mentioned in passing that ferric chloride solutions free from any suspended colloidal matter exhibit a noticeable magnetic birefringence.

Multiple Ionisation and Secondary X-ray Absorption Edges.

A good verification of the existence of multiple ionisation in X-ray spectra would be to find a secondary edge, corresponding to the simultaneous transition of one K- and one L-electron. This edge will be at a considerable distance from the main edge. Since in X-ray spectra the question of multiple ionisation is of great importance, I have undertaken to search for an edge produced by sulphur answering to the above mentioned condition.

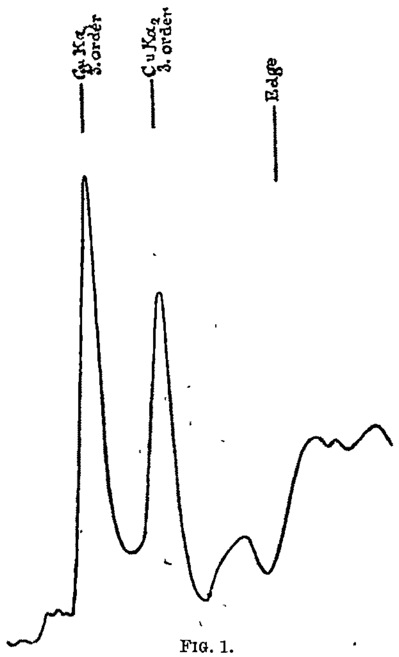

Fig. 1.

It is easy to calculate beforehand the approximate position of this edge. For sulphur the level M_{III} is incomplete. According to the selection rules,[1] a K-electron then jumps to M_{III}, but for an L-electron we have either $L_{\text{I}} \rightarrow M_{\text{III}}$ or $L_{\text{II, III}} \rightarrow M_{\text{IV}}$. However, since the three L-transitions will be difficult to separate and the difference between M_{III} and M_{IV} is small, we have only to consider the combined transition $\left\{\begin{matrix} K \rightarrow M_{\text{III}} \\ L \rightarrow M \end{matrix}\right.$. When calculating the energy of the L-transition, it should be noted that with one K-electron ejected the energy of an outer orbit should be estimated for an atom the nuclear charge of which is one unit higher than for the element considered. In the case of sulphur, we therefore use the L-energy value of chlorine. For the expected secondary edge we then find the wave-length to be 4635 X.U.; the value for the main K-edge being 5009 X.U.

Working with a Siegbahn vacuum spectrograph, the crystal being calcite, and pure sulphur as absorber, I found an edge with the wave-length 4644·0 X.U. There is a discrepancy between the observed and calculated values, the observed being 9 units larger, a discrepancy easily explained. First, the K-electron is not ejected to infinity; and secondly, the screening effect of the K-shell is not complete. Therefore the increase in nuclear charge as regards the remaining electrons is a little less than one unit. Hence the edge corresponds to an energy a little less than that calculated.

In Fig. 1 is shown a mean curve of three separate photometrical curves of one of the spectral plates. The two lines are copper $K\alpha_1$ and $K\alpha_2$ in the third order. They were used as reference lines. Between them and the new edge can be seen a region with increased blackening. Possibly another edge is to be found here, and further investigations may reveal its real nature. I also noticed an edge of this kind for the elements chlorine and calcium.

A fuller account of this investigation, now in progress, will be published in the *Zeitschrift für Physik*.

Isotope Effect in the Band Spectrum of Lithium Hydride.

In a recent paper,[1] I have analysed the band spectrum of lithium hydride. The general features of the band spectrum were somewhat different from ordinary molecular spectra, and definite edges or heads were hard to trace. Consequently, in the study of the isotope effect of lithium upon this spectrum, the vibrational isotope effect together with the rotational one have been examined in each line of the band spectrum.

The proportion of the two isotopes Li^7 and Li^6 should be about 13 : 1 from the chemical atomic weight 6·94 and Costa's values 7·012 and 6·012 for the isotope masses of lithium. Consequently, the expected isotope lines (Li^6H) should be found in the fainter lines which had not been classified in the former research.

The isotope effect is clearly established for each strong line in the spectrum due to the less abundant molecule Li^6H, the lines of which were found in their calculated positions within the error of measurement. This shows that our scheme in the numeration of the band spectrum of lithium hydride was correct.

Much experimental evidence concerning the relative abundance of the two isotopes has been offered by different workers. The results obtained by Thomson[2] and Dempster,[3] the former with the parabola method and the latter with a magnetic spectrograph and an ionisation chamber, showed that the relative proportion of the isotopes of lithium varied with the physical conditions, which are inconsistent with those obtained by Aston [4] and Bainbridge.[5]

In our optical method a definite change in the relative intensity of the isotope lines with the physical conditions has also been observed. At the initial stage of heating of the absorption tube, containing metallic lithium in a hydrogen atmosphere, lithium begins to combine with hydrogen, forming lithium hydride. In the absorption spectrum in such a condition numbers of fainter lines (those of $\mathrm{Li^6H}$) are greatly enhanced, the ratio of the two isotope lines ($\mathrm{Li^7H : Li^6H}$) being about 2 : 1. However, this value becomes larger as the vapour of lithium hydride tends to reach a stationary state up to about 8 : 1. This is in good agreement with the result of Dempster obtained by a different method and our latter value with 7·2 of Wijk and Koeveringe [6] from intensity measurements of isotope lines in the band spectrum of lithium. **Gisaburo Nakamura.**

Symbiotic Algæ of Corals.

In a recent contribution [1] Dr. C. M. Yonge, summarising his physiological work on corals published by the Trustees of the British Museum, took the opportunity to express his disagreement with Prof. Gardiner on the question of the significance of the symbiosis between corals and zooxanthellæ.

I am neither physiologist nor hydrologist, but it appears to me that Dr. Yonge may be basing on a false premise his argument that reef corals can get on quite well without the oxygen produced by the photosynthetic action of their zooxanthellæ. Dr. Jan Verwey, director of Den Helder Zoological Station, who has just returned to Europe after several years ecological study of corals in the East Indies, tells me that even when there is a good current flowing over a reef yet there may be a basal layer of very slowly moving water, so that a populous reef may easily suffer from a shortage of oxygen. It is, therefore, not by any means safe to assume that the movement of water round a reef always ensures a constant supply of oxygen.

Reviewing the ecological work of Vaughan, Mayer, and other Americans, the work of our own Great Barrier Reef Expedition, and that of a group of Dutch workers in the East Indies, it will be realised how rapidly our understanding of corals and coral reefs is being advanced. **A. K. Totton.**

Natural History Museum,
South Kensington, Sept. 3.

[1] Nature, 128, 309, Aug. 22, p. 309.

I have read Capt. A. K. Totton's letter and also Dr. J. Verwey's recently published paper [1] with the greatest interest. There can be little doubt that where reef corals grow in still water the oxygen produced by their zooxanthellæ may be of vital importance to them. Though here it must always be borne in mind that were not the zooxanthellæ present their place would be taken by a much more abundant phytoplankton continually producing oxygen in the water round about. But still water is seldom found (except during short periods of summer calms, and even then currents and upwelling continue) on the outer slopes of fringing and barrier reefs or of atolls, which are *the* essential areas of coral growth. In the case of the last two, indeed, which rise abruptly from deep water, there is frequently an upwelling of oxygenated water from deep waters as well as the continual agitation by the surf near the surface.

In enclosed areas, such as the Bay of Batavia, where Dr. Verwey has carried out his important work, or within atoll lagoons, the ability of corals to form reefs may well be controlled by the production of oxygen by their zooxanthellæ. But on the other hand, the vital factor even here may still be the removal of excretory products from the corals by the zooxanthellæ. It is very difficult to obtain adequate experimental proof one way or the other. For a long time during my work on the Barrier I believed that the production of oxygen by the zooxanthellæ was of vital significance to the corals, but, unable to obtain any adequate confirmation, I finally abandoned this belief. I hope to discuss the whole matter in detail in forthcoming papers in the Scientific Reports of the Great Barrier Reef Expedition.

Progress is certainly being made in the elucidation of the many biological problems connected with coral reefs, but each expedition raises almost as many problems as it, wholly or in part, solves. We are now, I think, nearing the solution of one most important problem, namely, the factors controlling the depth to which reef-building corals can live. For that reason I trust that an opportunity will soon present itself of making further progress towards the solving of this great oceanographical riddle, the key to which will probably be found in the nature of the relationship between reef-building corals and the zooxanthellæ. **C. M. Yonge.**

The Comma Butterfly in England.

The Comma butterfly *Polygonia c-album* died out in the east of England early in last century but survived in the west, and of recent years has been extending its range to the east again, reaching Twickenham in 1928.

A Comma visited *Sedum spectabile* in my Chiswick garden on Sept. 21, 22, 23, and 24, 1929.[1] In October 1929 it was recorded at Surbiton in the *Times*. This year on Oct. 5, 6, and 9 this butterfly has again visited *Sedum spectabile* in my garden, a fact which suggests that the species is establishing itself in the district. As a rule every September, tortoiseshells and red admirals come freely to *Sedum spectabile* here, but in the cold, wet month we have just had, the only visitor has been this rare butterfly. **F. Sherwill Dawe.**

Ashburton, 67 High Road,
Chiswick, W.4,
Oct. 9.

[1] Nature, 124, 653, Oct. 26, 1929.

Since the publication of Dr. Dawe's letter in 1929, a good deal of evidence bearing on the spread of *Polygonia c-album* in south-eastern England has accumulated. At that time, only one definite record for Kent (in 1916) could be found ; it has now been seen in East Kent (1929) and at Sandhurst (1930). In Sussex it appears to have established itself fairly securely along the South Downs about Chichester and Arundel, and also farther east at Lewes and Eastbourne. In Surrey, from which county it had not been reported in 1929, except for one record of an occurrence at Walton-on-Thames, it has since been met with at Sutton, Farnham, and Grayshott (1930), and at Mickleham (1931). In what might be termed the London district itself, in addition to Dr. Dawe's record, it was seen at Surbiton again, at Hounslow, West Wickham, and Gravesend in 1930, and even, as reported in the *Times* of Oct. 10, at Kensington in 1931. From the repeated occurrence of the butterfly on the western outskirts of London, one is forced to the happy conclusion that this attractive species must really have established itself somewhere in that neighbourhood, in many parts of which indeed its food plant, hop, grows fairly freely, more or less as a weed.

Change of the Dielectric Constant of Carbon Disulphide with Temperature.

H. ISNARDI [1] has found that the dielectric constant of liquid carbon disulphide increases linearly with the lowering of temperature, up to a maximum at - 90°, and then decreases also linearly with further lowering of temperature. This author has not, however, made a sufficiently careful study on the neighbourhood of the congelation point. His data do not permit us, therefore, to draw inferences as to the behaviour of the dielectric constant of carbon disulphide at its freezing point (- 112°).

On the basis of analogy with ethyl ether, I have supposed that at - 112° there appears a jump in the value of the dielectric constant of carbon disulphide independently of the maximum at - 90°. To check this supposition, I have made a study of the dielectric constant of carbon disulphide, using a method depending on the beats of two high frequency oscillation circuits, as described by M. Wolfke and W. K. Keesom.[2]

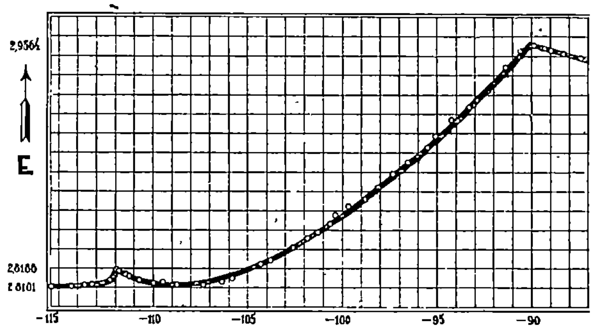

FIG. 1.

It appears that the value of the dielectric constant of carefully chemically purified carbon disulphide increases from 2·630 at 20° C. up to 2·936 at - 90° (maximum), and then decreases, to jump again at - 112°.

The accompanying curve (Fig. 1) represents these changes of the value. It can be seen that the dielectric constant of carbon disulphide behaves similarly to that of ethyl ether.[3]

Cosmic Evolution and Earthly Needs.

I IMAGINE that no journal has ever published even an approach to so wonderful a supplement as that to NATURE of Oct. 24 on "The Evolution of the Universe". The transcendental discussion reported is the more remarkable, as it is held at a time when ordinary folk are beginning to think that there may be difficulty in living much longer, in passable comfort, upon the pimple we are privileged to inhabit and are doing so much to spoil. From beginning to end, however, the British Association proceedings were Neroic: little effort was made by anyone to pay serious attention to our present earthly situation or to consider how we are to get out of the muddle 'science' has created. Pity 'tis that Sir Arthur Eddington did not "'eave 'is 'arf a brick" to this end. A century of science seems to have brought us to a wonderful understanding of things that do not matter, whilst 'larning us' little that will help to fill our bellies and suffer one another with equanimity, let alone gladly and with Christian amity.

The essays are not for the likes o' me to understand. Still, as a chemist, I should like Prof. Millikan to loan me a volt or two out of his visionary 25,000,000. He speaks of an atom-building act of this energy-order "that is more fundamental than all others and must take place more often than all others, . . . namely, the formation of helium out of hydrogen, because we have abundant evidence that all the elements are actually built out of hydrogen and helium", and so on. What is here meant by hydrogen? What is the process pictured? Have we such evidence? Physicists will use our words, unfortunately, in their own ways: as for example, *ion*, which is now used in so many ways that it means 'what you please', apparently. Whatever cosmic hydrogen may do in cosmic space, no laboratory hydrogen that we know gives helium, even in the Langmuir blowpipe.

While on words, may I take formal objection to my friend Dr. Aston's continued use of the term *constitution* when he means the *composition* of the mushes we still term elements. Constitution is used by the chemist only as implying structure in uniform materials.

HENRY E. ARMSTRONG.

Chemical Nature of the Tigroid.

THE chemical nature of the tigroid (Nissl's granules) of nervous cells is still unknown. On morphological grounds they are generally supposed to be related to the nucleus.

The brains of freshly killed guinea-pigs were fixed in alcohol, embedded in paraffin, and dissected. If stained with toluidine blue, the cells showed an abundance of tigroid. If, however, before staining, the slides were digested for thirty minutes with saliva, the cells no longer showed such granulation. This strongly suggests that the tigroid is a reserve polysaccharide of the nervous cells, similar to glycogen, but not identical with the latter, since it does not stain with iodine. This would be in good agreement with the disappearance of the granules after strong functional activity of the nervous system.

A more detailed report will appear in the *Acta* of the Hungarian Biological Research Station, Tihany.

Research Items.

Human Skulls and Bones from the Naga Hills.—The skulls and bones which are the subject of a report by Dr. B. S. Guha, anthropologist of the Zoological Survey of India, and Mr. P. C. Basu, published as the first *Anthropological Bulletin of the Zoological Survey of India*, were surrendered in 1926–27 to the expedition of the Burmese Frontier Service for the abolition of slavery and the suppression of human sacrifice among Naga tribes living in the unadministered area of Burma. The skulls and bones are those of human sacrificial victims from 41 out of the 70 villages in the Triangle which are under the influence of two Kachin families, the Ningmoi and the Shingbwiyang. Little information was available as to the tribe or place of origin of the victims, as they had passed through many hands and villages before reaching their destination. They would seem to have been forwarded from the south-west and west by middlemen engaged in the traffic. Though they probably belong to the head-hunting Naga tribes of south-west and west of the Triangle in the main, foreigners may have been included. At least one Assamese was sacrificed. Some of the heads had been smoked in accordance with custom, and each of the bones, some with flesh and shreds of skin still adhering, had been pierced by one or more holes for suspension. Some of the smaller bones were bound in lots. In one case a piece of skull and portion of radius were covered with leaves and bound to a bamboo which had two strings for suspension. The total number of bones was 217, of which 21 were whole, or portions of, arm and leg bones, and 117 and 43 were frontal and occipital bones respectively. The skulls and bones have been examined and measured exhaustively, the measurements being given in detail. The skulls fall into two classes, of which the first is markedly Mongolian, while the second in addition shows characteristics of the Australoid type.

Balun Bidai.—In the *Journal of the Federated Malay States Museums*, vol. 15, pt. 2, Mr. Ivor H. N. Evans records some information relating to a mythical aquatic animal, which will be of interest to students of folk-lore on account of analogous beliefs recorded from other parts of the world and from other times. While engaged in excavation work near Kuala Nyong, on the Timbeling River, Pahang, he was informed by his coolies of a curious mythical animal, known as Balun Bidai, which is supposed to live in a deep pool in the Timbeling. The word *balun* in the Malay language has the secondary meaning ‘ to roll as a mat or a cigarette ’. Further inquiry elicited the information that this mythical animal is also said to exist at Lahar Jintang, near Kuala Kitil, where it is known as Gulong Bidai. As *balun* and *gulong* are synonyms, the meaning in both cases is ‘ the enveloping chick ’ (native venetian blind), corresponding with the creature's reported habits. The Pahang Malays say that Balun Bidai is rectangular like a mat, with a mouth at each corner, and is ginger coloured. It used to attack boats on the river, wrapping itself around them. It lives in deep pools in rivers and brings up great masses of rubbish “ as big as a house ”, which are said to be quite dry when brought up. None of the coolies claimed to have seen it but one had seen the masses of rubbish. One of the animals is said to live at a village in Lower Perak called Balun Bidai, not far above Kuala Kinta. At Batu Kurau, Larut, Perak, Gulong Bidai kills men by enveloping them and sucking their blood, though leaving no wound.

Birds of the Galapagos Islands.—In 1905–6 an expedition was made on behalf of the California Academy of Sciences to study and collect the fauna and flora of these islands. The report on the bird collections by Harry S. Swarth is a memoir of ecological as well as taxonomic importance (*Occ. Papers Calif. Acad. Sci.*, **18**, 1931). There are 108 species and subspecies of birds in the Galapagos list. Eighty-nine are breeding and resident upon the islands, and of these the very large proportion of 77 are peculiar to the islands. The author supports the view that when the bird fauna arrived, Galapagos was already an island group, for although the birds which show clear affinities point unmistakably to American relationships, the islands are remarkably destitute of the highly characteristic bird life of the adjacent coast of South America. A very great amount of variation, however, has taken place since the islands were colonised by birds, and although the variations exhibit many extremes, intergradations between the extremes can always be traced, but not always between geographically adjacent forms. The extraordinary variants that crop up in many of the series, for example in the bill structure of *Geospiza fortis* and *fuliginosa*, give an impression of a process of change and experiment still going on. Here, in the very islands that aroused his mind to the possibility of evolution, appear to be the “ numerous transitional forms ” and the confusion in Nature, which Charles Darwin expected and looked for in vain.

Food of Australian Aborigines.—That a primitive people like the Australian aborigines should be skilled in Nature lore is not surprising, but the variety of methods they have devised in capturing food animals is a striking feature brought out in C. Daley's account of the “ Food of the Australian Aborigines ” in the *Victorian Naturalist* (June 1931). Kangaroos were captured by stalking, by tracking to exhaustion, by pitfalls, or by driving into corral-like enclosures. Wombats were smoked in their burrows ; emus were stalked, netted or run down by dogs; smaller birds were lured, or snared or captured with large nets, in the case of water-fowl up to 60 yards long. Crocodiles were taken with a slip-noose or speared, as were tortoises, turtles and dugongs. Fishes were trapped with a great variety of apparatus, or speared at night with torches, after the manner of our own salmon ‘ leistering ’, or they were impounded in artificial weirs or stone dams. The honey stores of wild bees were discovered by marking a bee by attaching a piece of white down to it, and tracing its flight home, and so on. The above gives some notion of the variety of food used by the aborigines, but a more vivid picture is contained in Major Mitchell's account of the contents of a ‘ lubra ’ or plaited bag of almost a hundred years ago : “ three snakes, three rats, about 2 lb. of small fish like whitebait, crayfish, and a quantity of the small root, tao, usually growing on the plains with a bright yellow flower, *Microseris Forsteri* ”. Nothing seems to come amiss, for, particularly in Queensland, clay from the outside of ‘ ant-hills ’, or kaolin, is freed from grit, made into a smooth stiff paste, dried, wrapped up, subjected to heat, and is much appreciated as an article of food.

Anal Gland of *Squilla*.—T. Komai and Y. M. Tung have examined the anal gland of *Squilla* (*Mem. Coll. Sci.*, Kyoto Imp. Univ. Ser. B, vol. 6, No. 1, 1931), which consists of two pairs, an anterior and a posterior, of small sacs communicating with the posterior end of the mesenteron by short ducts. The cells which compose the wall of each sac are secretory. The cells of the anterior sac are vacuolated, and in the lumen is either a number of secretory spherules or more usually a single concretion, formed of concentric layers, which is eventually passed out by the duct into the gut and so to the exterior. In the posterior sac the secretory substance is liberated as a vacuole constricted off from the distal part of each cell and no concretion is formed in this sac. The authors regard the sacs as carrying out the excretion of waste products in the posterior region of the body, acting as auxiliaries to the maxillary glands which are the primary excretory organs. In *Squilla* the proctodæum, which forms the rectum, is short—1·2 mm. in length. Details of the anatomy of the heart and the distribution of the arteries of *Squilla* are also given.

The Gondwana System.—A most important and interesting contribution to the geology of Gondwanaland has been written by Dr. C. S. Fox and published as *Mem. Geol. Surv. India*, vol. 58, 1931, pp. 241. It includes a summary of all the available information on the Gondwana System. This ' system ' represents more than a geological period; its formations cover a time interval from the Upper Carboniferous to the Lower Cretaceous, and thus represent an *era* which cuts across the division between Palæozoic and Mesozoic. The general classification now adopted in India consists of two chief subdivisions: Lower Gondwana (Talchir, Damuda, and Panchet) and Upper Gondwana (Mahadeva to Jabalpur), but the break occurs, not between the Permian and Triassic, but in the middle of the Triassic, when there was a cessation of effective sedimentation owing to widespread land conditions. Weighty evidence is presented to justify the abandonment of the tripartite classification formerly widely accepted. The climatic changes of Lower Gondwana times can be traced from the ice wastes of the Talchir epoch, through the damp, temperate conditions of the Damuda period, to the hot arid climate of the Panchet age. Following the regional uplift that marks the break, there was a return to humid conditions in Upper Gondwana time. The lake-waters of Central India found their way to the sea that was established during the Jurassic over the site of the Bay of Bengal, and later, especially in the Cretaceous, to the sea that extended from the west to Kathiawar. The valleys that then were formed were filled to overflowing with the lavas of the Deccan trap, and from then to the present day laterite formation, characteristic of tropical monsoon conditions, has been active. The memoir is enriched with a large correlation table, four palæogeographical maps, and a fine series of plates illustrating the plant life of Gondwanaland.

Cohesion.—The issue of the *Proceedings of the Physical Society* for Sept. 1 contains the address on " Cohesion " delivered by Prof. Lennard-Jones before the Society in May last. In it he shows how much the new wave mechanics has contributed in the last three or four years to our knowledge of atomic structure and of the interaction between atoms, in directions in which the orbital theory of the atom could provide no information. Many atoms may be pictured as globular clouds in which the density of the cloud at any point is proportional to the probability that an electron may be present in unit volume about that point. The motion of an electron in one atom tends to make an electron in a neighbouring atom move on the average in phase with the first, and this produces an attraction between the atoms inversely proportional to the seventh power of their distance apart and a slight deviation from the perfect gas law. This attraction is usually masked by the much greater one resulting from the migration of an electron from one atom to another, which in some cases is sufficient to produce the firm structure of a solid. These ' homopolar forces ' are shown to follow from the expression for the joint probability that an electron may be found in each of two specified small volumes. They are intimately connected with the spin of each electron, and the cohesion which results from them depends on whether these spins are in the same or in opposite directions. In the latter case the electrons are said to be paired, and the pairing of electrons provides for the valency rules of chemistry. (See also NATURE, vol. 128, p. 462, Sept. 12, 1931.)

The Cosmical Constant and the Wave Equation.—Sir Arthur Eddington has contributed a paper to the October issue of the *Proceedings of the Royal Society* in which he has attempted to weld together in a new way the ideas of the quantum theory and of the cosmical relativity theory. His idea is that the appropriate space-time in which the wave-equation for an electron should be considered valid is not the flat system which is ordinarily employed, but the more general and cosmically important curved space-time. So long as the former is employed, no light can be expected to be thrown on the nature of the term in the wave-equation representing the mass, but by introducing the latter the mass-term can be incorporated into the theory. The step involved is not really foreign to the ordinary ideas of quantum theory, for it is a fundamental conception in this that particles cannot be considered individually, but that their behaviour is conditioned to a greater or less extent by all other particles in the universe. The mass of an electron thus becomes an interchange energy with all the other charges in the universe suitably averaged. The mathematical development, which is indeed not very elaborate, leads, fortunately, to a prediction that can be tested experimentally from the speed of recession of the spiral nebulæ, Hubble's value of 465 km. per sec. per megaparsec being obtained to within fifteen per cent.

Ultra-Violet Spectrum of Ozone.—An investigation of the effect of temperature on the ultra-violet absorption spectrum of ozone, described by O. R. Wulf and E. H. Melvin in the second issue of the *Physical Review* for July, may be of importance in meteorology. The spectrum consists of diffuse bands on a continuous background. It has been shown that the relative intensity in the bands and background depends upon the temperature of the ozone, the contrast between the two increasing when this is reduced from 250° to $-78°$. The alteration is not large, but may, nevertheless, have a bearing on the interpretation of the changes observed in ultra-violet solar and stellar spectra, if fluctuations occur in the temperature of the ozone in the upper air. Alternatively, it may prove possible to obtain a new estimate of the temperature in the ozone layer from the appearance of the bands, and it is noteworthy that Prof. A. Fowler and Lord Rayleigh have stated that the bands are, as a whole, more diffuse in the photograph of Sirius than in the laboratory spectrum. Barring other complications, such as an effect of pressure, this could be taken to indicate that the temperature of the ozone layer was higher than that of the laboratory.

The Atomic Weight of Thallium.—A revision of the atomic weight of thallium which is in close agreement with Honigschmid's value, but markedly different from that of Crookes, is described by Prof. H. V. A. Briscoe and a number of collaborators in the October number of the *Proceedings of the Royal Society*. Crookes's work, which was published in 1873, was based on a determination of the ratio $Tl : TlNO_3$, and gave $Tl = 204·04$. This held the field until quite recently, when Hönigschmid, employing thallium halides and silver in a very concordant series of measurements, found the higher value 204·39. Prof. Briscoe, employing the ratio TlCl : Ag, has now obtained as a final result 204·34, with an average deviation of ±0·015. Apart from one point of technique—the fusing of thallium chloride in place of the process of sublimation adopted by Honigschmid—Prof. Briscoe makes no special claim for his own result in preference to that of Honigschmid, and suggests that the actual value is within one or two hundredths of a unit of 204·37. The large departure of the atomic weight from a whole number shows that it is a mixture of isotopes, a conclusion which is confirmed by Dr. F. W. Aston's announcement in Nature of Oct. 24, p. 725, that the mass-spectrum indicates two isotopes, of atomic weight 203 and 205 respectively.

New High Permeability Alloys.—Ordinary 'permalloy', the alloy of iron with 78·5 per cent of nickel, is specially suitable for direct current circuits. For A.C. circuits a higher electrical resistance is desirable to minimise eddy current losses, and in the *Bell Laboratories Record*, Sept. 1931, vol. 10, No. 1, G. W. Elmen gives an account of work done on similar alloys in which part of the iron is replaced with chromium or molybdenum. Both these elements increase the resistivity, and with 3·8 per cent peaks are obtained in the curve of initial permeability, which in the case of molybdenum actually rises above that for the original alloy. Above a flux density of about 2000, however, the plain nickel-iron alloy is the more permeable. This latter alloy also suffers from the disadvantage that in addition to an annealing treatment at about 950° C., further heat treatment at 600° C. followed by rapid cooling is necessary if the full magnetic qualities are to be developed. With some of the newer alloys the original annealing is unnecessary, and slower rates of cooling give the highest values of the permeability. It is of interest that the addition of a non-magnetic metal such as molybdenum may, in certain circumstances, render a magnetic alloy still more magnetic. For the annealed alloy, 3·8 per cent of molybdenum gives an initial permeability of 12,000, and when heat-treated in hydrogen, of 35,000, values far higher than that of ordinary 'permalloy' in the annealed state and three to four times that even of the material in the heat-treated condition. As the molybdenum content is raised, the Curie point—the temperature at which the alloy loses its magnetisability—is reduced, which is in accord with the general rule that the addition of a non-magnetic element to a ferro-magnetic one lowers the Curie temperature. It is concluded that no one such alloy is the best for all purposes, and that a range of materials will be developed each suitable for some specific electrical purpose.

Astronomical Topics.

Galactic Rotation.—Prof. P. Stroobant, Director of the Uccle Observatory, has been making a study of the radial velocities of the helium stars (types B_0 to B_7) in connexion with the problem of galactic rotation (*Bull. of Acad. Roy. de Belgique*, 1930, No. 10). His results indicate galactic longitude 141°, or 321° for the centre; the work of others leads to the selection of the second value. The centre is placed at a distance of 9250 parsecs from the sun; adopting 270 km./sec. as the sun's rotational speed, the period of rotation would be about 200 million years. The central mass required to control the motion is given as 16×10^{10} sun. The diameter of the galaxy is estimated as 23,000 parsecs. The Uccle Observatory is soon to have a new telescope with an aperture of a metre: also a new transit circle. Prof. Stroobant hopes to continue the research with the aid of these instruments.

The Variability of Betelgeux.—Sir John Herschel seems to have been the first to discover that this star was a variable. But it was not until the present century that any law was detected in its light changes. The evidence on the subject is collected and reviewed by B. W. Kukarkin in the *Bulletin of the Friends of Astronomy*, Nishni Novgorod, for June. A period somewhat less than six years is plainly shown by the curve that he gives. The observations of radial velocity at the Cape are of great use in the determination, as the change in this appears to be more regular than that in the light; but evidently both have the same period, which is given as 2070 days, or 5·67 years. The variable radial velocity is ascribed not to orbital motion but to expansion and contraction of the star. Assuming this, and taking the parallax as 0·015″ (which is the mean of the best five values), the radius of the star is found to change from 262 to 416 times that of the sun; this would make the diameter of the star change from 0·037″ to 0·058″, in fair agreement with the values given by the interferometer.

Both the radial velocity results and the light measures suggest that secondary oscillations may be superposed on the curve of principal variation, but the data are insufficient for determining them. The amplitude of the light-variation is close to 0·7 mag., but may be variable; in visual observations of brightness a comparison star at some distance has to be used, which adds to the difficulty. Aldebaran is often chosen, being of similar colour.

Quite a number of the red stars easily visible to the naked eye are variable; but comparatively few observers devote themselves to these bright objects; it is necessary in their case to use comparison stars at some distance, which adds somewhat to the difficulty. *Astr. Nach.*, No. 3817, contains a series of such observations, made at Prague by J. Mrazek and J. Plassmann.

The observations of α Herculis range from $2·73^{\mathrm{m}}$ to $3·88^{\mathrm{m}}$; those of Betelgeux (which was compared with Aldebaran) from $0·41^{\mathrm{m}}$ to $1·34^{\mathrm{m}}$; those of β Pegasi from $2·35^{\mathrm{m}}$ to $3·25^{\mathrm{m}}$. Unusually short intervals from maximum to minimum were noted in α Cassiopeiæ in 1927 and 1928; the maxima were on July 22, 1927, and July 8, 1928; the minima were 8 days and 7 days later, respectively.

Elements of the Trojan Planet Æneas.—Three new members of the Trojan group of minor planets were found in 1930. Æneas was found by Dr. Reinmuth at Königstuhl, Heidelberg, on Oct. 17, and was followed for five months at that observatory and at Yerkes by Prof. G. van Biesbroeck. C. J. Krieger has investigated its orbit, and gives the following elements in *Astr. Jour.*, 960:

Epoch 1931 Jan. 1·0 U.T.
M 97·7850°
$$\left.\begin{array}{ll}\omega & 45^\circ\ 2'\ 12·1''\\ \Omega & 246^\circ\ 31'\ 59·0''\\ i & 16^\circ\ 40'\ 32·3''\end{array}\right\}1931·0$$
e 0·100455
a 5·21903
n 297·592″

The mean position of the planet is 60° from Jupiter on the side of smaller longitude. There are now four known Trojans on this side of Jupiter and five on the other. It will be noticed that the mean distance of Æneas is practically the same as that of Jupiter; but owing to its large eccentricity its distance from Jupiter will fluctuate through about 12° on each side of the mean value.

It is curious that another Trojan planet, Anchises, was discovered on the same photographic plate as Æneas.

Modern Glasses at the Science Museum.

AN Exhibition of Modern Technical and Artistic Glasses at the Science Museum, South Kensington, to remain open until the end of the year, was formally opened on Oct. 21 by Sir Richard Gregory (see NATURE, Oct. 24, p. 697). The organisers, who represent the Society of Glass Technology and the Glass Research Delegacy of the University of Sheffield, have endeavoured in this exhibition to illustrate the more striking advances arising from scientific studies in glass technology during the past fifteen years. In doing so, it has been necessary, in view of the limitations of space, to make a selection of the subjects which are comprised within the term 'glass technology' and a further choice of material even in those subjects represented. Thus, in the main, the problems involved in the manufacture of glasses in modern times which have given rise to many important researches, such as the solution of gases in molten glasses, and the diffusion and flow of viscous liquids at high temperatures, receive no attention, and it has not been found possible to find space for exhibits illustrating researches on raw materials, on the special characteristics of refractory materials required for various manufacturing conditions, and the applications of glasses to the many types of scientific apparatus.

In general, the exhibition may be said to illustrate the relationships between the chemical composition and the physical properties of glasses, with indications of the industrial results of the researches involved. Fourteen sections are employed in classifying the subjects dealt with. Section *A* comprises a review of the most important literature on glasses (excluding works on optics and optical instruments) which has been published since 1915. In this collection are the journals of scientific bodies devoted to the study of glasses, trade technical journals, technical books, and works devoted to the historical and artistic side of glasses. Sections *B* to *E* are concerned with fundamental properties of glasses; *F* to *O* illustrate how the results of fundamental researches on the relationships between chemical composition and physical properties have been utilised in recent developments in the production of specific types of glasses, the types dealt with including coloured glasses for artistic and utilitarian purposes; optical, chemical, heat-resisting, illuminating, and electrical glasses; sheet and plate, safety or laminated, and fused silica glasses. Specimens, photographs, and numerous diagrams of data are employed to convey information to the visitor.

It is impossible to do more than refer to a few of the more interesting results of modern work. Section *B* is devoted to the nature of glass, and illustrates, amongst other matters, the study of the equilibrium diagrams of the complex systems in which glasses fall, and some pretty specimens of crystallisation from glasses are shown. The effect of heat treatment on crystal growth is set out pictorially. A whole case is also devoted to the most modern methods and results of the study of the nature of glasses by the X-ray method. Section *C* contains many interesting specimens, Roman, medieval, and modern, which have undergone weathering and decay as the result of unsuitable composition; and modern researches which have shown the way to produce very durable glasses are described and illustrated. Section *D* is devoted to certain physical properties of glasses. Particular attention is paid to modern work on the thermal expansion; and in this sub-section are shown examples of graded glass seals which enable a glass of low thermal expansion to be united to one of high expansion through intermediate joints, and of glass to metal joints. The mechanical properties of glass are illustrated, and types of fracture produced by thermal and mechanical forces are exhibited. The low thermal conductivity of glass is further reduced when drawn into a mass of fibres with intervening air spaces, and British glass 'silk', shown in various forms, is coming into widespread use for heat insulating purposes.

The most spectacular of the sections is *F*, dealing with the colouring and decolourising of glasses. The six cases devoted to this subject stand in the entrance hall of the Museum and at once arrest the eye. The first case starts with some beautiful specimens of coloured Egyptian glasses of the Eighteenth Dynasty. Below them, and extending to the second case, are numerous specimens, specially melted at the Department of Glass Technology, Sheffield, to illustrate the tremendous range of colouring materials available to the modern glassmaker. More effective illustrations of colouring than these are the specimens of artistic glasses. Three roses, with glass petals of white, pale yellow, and rich red, respectively, simulate the real flowers to a remarkable degree. Amongst the more striking colouring agents in the artistic glass exhibited are selenium (various shades) and the oxides of didymium, neodymium, and praseodymium. The utilitarian division of Section *F* includes such objects as Crookes glasses, various protecting glasses for furnace workers and welders, signal glass, and colour filters. An offshoot of this section is that devoted to illuminating glasses (*L*), where 'daylight' lamps and other objects are shown. Also in section *M* (sheet and plate glasses), reference is made to research on coloured glasses suitable for keeping away flies.

Toughened glass samples appear in Section *L*, and are referred to in Sections *E* and *J* also. The nature, methods of manufacture, and sources of defects in 'safety' or laminated glass are well set out in Section *N*. The neighbouring Section *O* (fused silica) contains a number of historical specimens, as well as others showing that many massive, as well as small, objects of fused silica are now obtainable.

Three cases are devoted to optical glasses and one to optical lens systems. One of the most important advances has been the improvement in transmission both in the ultra-violet and in the infra-red brought about by painstaking efforts to reduce the iron oxide content. A massive specimen shown contains only 55 parts of iron (as Fe) per million of glass, and it is claimed that British optical glass is now superior to any other in regard to transmission at both ends of the spectrum.

Foot-and-Mouth Disease Research.*

THE Fourth Progress Report of the Foot-and-Mouth Disease Research Committee, just issued, is a record of extremely interesting observations and experiments. We agree with the Committee when it says that "the knowledge of foot-and-mouth disease and the conditions which promote the infection and the means of its prevention have been materially advanced by work in many parts of the world, and that the researchers in this country have taken their fair share in furthering that progress". It is true that we have still no very clear vision of the time when scientific methods of prevention and spread are to be substituted for slaughter. The causal virus is familiar and the disease can be produced experimentally with it. Further, it has been clearly demonstrated that with this virus, weakened in various ways, immunity against the disease can be produced. This immunity, however, does not seem to last very long, and until the virus can be grown on artificial media, sufficient of it cannot be obtained to do a very large series of immunisation experiments. The work of Prof. and Mrs. Maitland in Manchester gives us hope of culture, for they have shown quite conclusively that multiplication of the virus will take place in the presence of living embryo tissue of guinea-pigs. This is a decided advance.

---

* Ministry of Agriculture and Fisheries. Fourth Progress Report of the Foot-and-Mouth Disease Research Committee. Pp. 375+12 plates. (London: H.M. Stationery Office, 1931.) 7*s*. 6*d*. net.

Further evidence is given in the Report of the different types of the virus, but the most encouraging fact in relation to treatment, especially serological treatment, is that 92 per cent of the strains obtained from outbreaks in Great Britain belong to the *O* type. If, therefore, we were able to obtain an anti-virus of this type, we could deal hopefully with almost all the cases that occur.

Much valuable information has been collected on the survival of the virus in sewage, in milk, in carcases after storage at different temperatures, and of its resistance to pickling, etc. In administrative work these results should prove of great importance. Again, the infection of rabbits, hedgehogs, and rats opens up a suggestive field for investigation of the method of spread. In 1924, I reported to the Committee the results of experiments by myself and colleagues which showed that rats could be infected with the disease, confirmed this by further reports in 1928, and suggested that the rat, by its migratory habits, might be a carrier. The infection in rats has now been fully confirmed by the Committee, and in a note on the origin of fresh outbreaks it is stated that "the discovery of very inconspicuous signs of the disease in rats must increase the care with which symptoms of infection in these animals are sought, and add fresh importance to the warfare waged against these animals". To the farmer and dairyman this possible carriage is of the utmost importance.

The whole Report is full of interest, and the scientific workers under the Committee are to be congratulated. All their work is leading to the goal of prevention. J. M. BEATTIE.

Cotton Growing in Egypt.

DR. W. L. BALLS and his assistants in the Botanical Section of the Egyptian Ministry of Agriculture have published within recent years two bulletins on the "Operation of the Seed Control Law upon the Pedigree of Cotton Seed".* The first is a survey of the effect of the control during the first two years, and the second includes the first and extends the period to four growing years from 1926 until 1930. Egypt supplies the bulk of cotton for the fine spinning industry, in which quality is of great importance, and competition with lustrous fabrics made from synthetic fibres is making the use of good quality cotton more and more essential.

It would appear that the maintenance of the purity of good strain cottons is desirable for both the farmer in Egypt and the spinner in England, and that little difficulty should be met in operating a law designed to help in securing plentiful supplies of high quality pedigree stocks. Unfortunately, the tests applied by the botanical staff show that as the law becomes better known, methods of evasion are discovered and practised. Cotton seed is used both for growing and crushing, and it is this dual purpose which leads to malpractices. The law has improved commercial stocks with commendable rapidity, and the method of evaluating the improvement, and incidentally of detecting evasions, is surprisingly simple. There exists in Egypt a low quality cotton, known as Hindi, which is very easily recognised when growing and also in seed form. The percentage of Hindi seed has been found to be a very good index of the amount of contamination in seed stocks. A simple count is all that is required, and the method of plotting these counts shows very vividly how the law is operating.

The curves in these publications are so easily interpreted that it is possible to obtain from them the maximum allowable Hindi-content from year to year, although the legal limit has been reduced yearly to a very low percentage. There can be little doubt that deliberate adjustment of the Hindi-content to fall with the legal limit is being practised, but if mixing could be kept within the limit the purpose of the law would be fulfilled. There are many cases where the Hindi-content is well above the limit, and the system of analysis employed is searching enough to locate the law-breakers with scientific if not legal conviction. It seems that the offenders can only be made to mend their ways if the penalties for evasion are as carefully regulated as the system of diagnosing the culprits. While the Hindi-content is a simple and reliable index of either careless or deliberate lowering of the standard of purity of the seed stocks, it is not a true index of the purity of the cotton types, as natural crossing and other deteriorating influences are unavoidable in large scale cultivation.

The botanical staff clearly recognises that the most effective way of cleaning commercial stocks is by renewal of seed from clean stocks, and the methods adopted to achieve this are given in a bulletin entitled "Developments of the Existing System for Seed Supply of Cotton in Egypt".* Perhaps the most interesting technical item in this publication is the use of large cages of high light-transparency made of fine 'staybrite' steel wire, for the propagation of pure types. The mesh is fine enough to prevent natural crossing, and improvement in the design and production of these cages has advanced to the stage when the cost per unit area covered is little more than the cost of the pre-War cages made of corrodible wire.

The raising of sufficient seed from such small cage stocks to supply the extensive growing areas of Egypt is a story in itself, and the scientific organisation of the expansion process leads us almost to accept the statement that the botany of the cotton plant is better known than that of any other plant. It might be contended that the method of seed renewal is adequate for the maintenance of clean stocks, and that the pruning effect of the seed control law is antithetical. Assuming it is possible to provide adequate seed supplies from reliable sources at one or two years' remove, accident or carelessness will lead to premature contamination, but if all concerned in the handling of the stocks are compelled by rigorously enforced law to exercise necessary care to prevent mixing, the burden of seed renewal will be lightened. Pruning and seed renewal are thus complementary, and all who have an interest in the prosperity of the cotton industry will wish success to the botanical and agronomic sections in Egypt in their efforts to improve by both means the quality and uniformity of cotton seed stocks. F. P. SLATER.

The Study of Forest Entomology in India.

THIRTY years ago the entomology of the forests of India and its study were still a closed book. Types of forest insects had found their way into the national museums and private collections in Europe, and thus received a name. But, as became apparent during the first decade of the present century, numbers of the insects of forest importance, as probable or possible pests, were unnamed and their biology unknown. The early pioneer work of the forest officers who were first set to grapple with the position proved by no means easy, but extraordinarily fascinating.

In India, during those first few years, the assistance of a dozen or two expert systematists was required to enable progress to be made at all, and the preliminary publications of results (expected by and demanded by Government) to be issued.

The *Indian Forest Records*, parts 9 and 10 (Calcutta: Government of India Printing Office, 1930), afford a typical example of this progress. Both these parts are devoted to the genus *Xyleborus*, a genus of wood borers (the so-called pinhole and shothole borers) well known to foresters. In part 9, Hans Eggers, of Stolberg, Harz, Germany, discusses "Neue *Xyleborus* Arten (Col. Scolytidæ) aus Indien". In this paper the author describes some forty new Indian forest species, and also proposes a new genus, *Pseudoxyleborus*, in which he describes one species, *P. Beesoni.*

Part 10 of the *I.F. Records* is written by Dr. C. F. C. Beeson, forest entomologist at the Dehra Dun Research Institute, and is entitled "The Biology of the Genus *Xyleborus*, with more New Species". Chap. i. is devoted to the new species, and is indicative of the valuable knowledge we now possess upon this important genus.

Chap. ii. is devoted to the main theme. "The present *Record*", the author says, "summarises the available biological information on Indian species of *Xyleborus*, their regional distribution, food plants, life histories, and gallery patterns." The importance attached to the systematic study of groups of pests of this type, if solely from the economic point of view, will become evident from the following remarks: "Pinholes and shotholes in timber in India are made by a specialised group of borers (often called 'ambrosia beetles') comprising the extensive genus *Xyleborus*, as also *Webbia* of the family Scolytidæ, and Crossotarsus, Diapus, and Platypus of the family Platypodidæ. The term 'pinhole' is applied to holes the size of a pinprick and 'shothole' to holes corresponding in size to various small shot up to 3 mm. in diameter; otherwise there is no fundamental difference in the mode of origin of the holes or in the habits of the borers in making them. The tunnels are bored in wood by the female beetle, and the wood-dust resulting from their excavation is thrown outside, so that a free space is provided in which eggs are laid and the larval breed is reared to maturity. Unlike the majority of borers of timber, the larvæ of ambrosia beetles do not feed on wood, but on fungus (the ambrosia) that grows on the walls of the tunnel in a mycelial layer of variable thickness and produces highly nutritious fruiting bodies. Tunnels that have been occupied for a short time get stained black, and in some species secondary saprophytic fungi develop, that discolour the wood vessels for a little distance around the tunnel. Timber that has been attacked by pinhole and shothole borers thus shows defects in the form of black spots and lines on the sawn surfaces, which spoil it for ornamental purposes and for special uses as matches, veneer, plywood, etc.; unless heavily attacked, it is not seriously weakened for structural purposes."

The paper ends with an excellent index to food plants of Indian species of *Xyleborus*. The author is to be congratulated upon an excellent piece of work.

Of a different type, emanating from the same research branch at Dehra Dun, is the series of papers dealing with the immature stages of the Indian Coleoptera, by Mr. J. C. M. Gardner (*I.F. Records*, Entom. Ser., vol. 16, part 3, 1931). Mr. Gardner produces his eighth paper, "*Cerambycidæ* (Continued)", which completes the description of the identified material in the Dehra Dun collections. The classification of the family Cerambycidæ, and, says the author, "especially of the sub-family Laminæ, has always presented difficulties to workers, who have relied almost entirely on the external morphology of the adult; the study of immature stages should help in a more satisfactory phylogenetic grouping of genera. So far, attention has been concentrated on larvæ, but the pupal stage certainly deserves more attention than it has received."

That Indian research work should be giving what might almost be termed a lead in a branch of study which may prove of considerable practical importance, would seem to merit being placed on record. Certainly, Mr. Gardner's admirable and patient work should enable the forest officer out in the forest, or in the temporary timber depot, to recognise a pest, abundantly represented by the larvæ in the timber but with no trace of the perfect insect; a position only too well known to many forest officers.

Palæolithic Flint Implements.

IN the course of the work in southern Palestine of the British School of Archæology in Egypt, a large number of palæolithic implements of early type have been collected near Gaza. A number of these were exhibited at a meeting of the Royal Anthropological Institute about two years ago by Sir Flinders Petrie, and it was then determined to submit them to Mr. Reid Moir for inspection and report.

In making his report, which is published in the Institute's *Journal* (vol. 60, pt. 2), Mr. Reid Moir finds that the implements fall into two clearly defined groups. The first consists of massive specimens, produced by the removal of thick wide flakes, and much abraded: the second is formed by the detachment of thin flakes tending to be of greater length than width, for the most part showing no sign of abrasion and clearly the product of a different technique. The difference in morphology is fundamental. Mr. Reid Moir considers that the first group belongs to the series worked out for East Anglia by him, which exhibits the transition from the rostro-carinate to the earliest palæolithic hand-axe. Rostro-carinates and transitional forms have been found in Uganda, Rhodesia, India, and now Palestine. Notwithstanding the fact that the Palestine implements have not been found in any ancient deposit, Mr. Reid Moir is still inclined to assign them to the early Pleistocene. The second group is classified as Acheulean, comparable with Acheulean implements of the second inter-glacial in East Anglia.

This conclusion raises the question, as Mr. Reid Moir puts it, "how to account for the presence in southern England and in Palestine of groups of flint implements made upon precisely the same definite and specialised plan". It seems scarcely probable that a race of people in Palestine worked out a series of this kind of flint implements on exactly the same lines and produced identically the same technique as another race living in southern England and—unless the early Pleistocene age of the Palestine implements is accepted—at a much later date. Mr. Burkitt, in discussing implements from India (see *Antiquity*, September 1930), compared them with implements from South and East Africa, and suggested that they were on a periphery of distribution of a single industry. Mr. Reid Moir is now strongly inclined to the view that the implements of Early Chellean type from Africa, India, and Palestine are to be referred to the same age as those in England, the early Pleistocene, and that at certain periods of past geological time stone implements were being made on the same highly specialised plan over enormous areas of the earth's surface, having started from a common centre. Hence it is not surprising to find that Mr. Reid Moir accepts the almost inevitable corollary that in the conditions governing movement, whether of culture or of race, at this early age, great periods of time must have been involved, with the implication that in most of the current computations man's antiquity is much underestimated.

Development of Weather Forecasting.

The *Quarterly Journal of the Royal Meteorological Society* for July 1931 contains an interesting survey of the present position of weather forecasting, by C. K. M. Douglas. The author pays tribute to the work of J. Bjerknes and other Norwegian meteorologists, who have developed in greater detail the system of analysis of synoptic weather charts according to the past history of the different air streams begun by Shaw and Lempfert many years ago in "The Life History of Surface Air Currents". He points out that for short-period forecasting the value of the method is undoubted, especially for periods up to twelve hours ahead. Any adequate discussion, however, of practical forecasting must always take note of peculiar tendencies observed, at least in European weather, described as 'persistence of type' and 'mood'. An excellent example of the first is mentioned, that of the severe spring snowstorms of April 2 and 11, 1917. The synoptic charts that accompanied these storms are said to have had features in common not shared by any other charts during the present century. The second tendency is for rain to be absent in certain seasons when the distribution of pressure is such that in an ordinary year it would be accompanied by rain at that season.

The mere recognition of these two tendencies does not greatly help the forecaster, but does indicate a line of research that might lead to important advances. In the case of persistence of type, it may be that by using synoptic charts covering a very wide area, most cases where a particular type of pressure distribution over, say, the British Isles and the North Sea appears to return after an interruption of two or three days, there will be seen to be a distribution of pressure over a much larger area that has been persistent during the interruption, the latter appearing as a mere local disturbance.

'Mood' is less easy to explain, and very difficult to investigate with our present limited information about the upper atmosphere, if, as seems probable, it is due, as the author suggests, to long-period fluctuations of temperature and humidity in the upper atmosphere.

University and Educational Intelligence.

Cambridge.—The treasurer of the University has received a cheque for £1000 from the Worshipful Company of Goldsmiths, for the better equipment of the Metallurgical Laboratory.

Mr. J. W. A. F. Balfour-Browne has been elected to a Frank Smart studentship in zoology at Gonville and Caius College.

At St. John's College, G. Bateson and R. O. Redman have been elected to fellowships. Mr. Bateson is an anthropological student, while Mr. Redman is assistant director in the Solar Physics Observatory.

For the eleventh year in succession, Trinity College announces the offer of a research studentship open to graduates of other universities who propose to come to Cambridge in October next as candidates for the degree of Ph.D. The value of the studentship may be as much as £300 a year. The same College offers, as usual, dominion and colonial exhibitions to students of dominion and colonial universities who wish to come to Cambridge next October as candidates for the degree of B.A., M.Litt., M.Sc., or Ph.D. These exhibitions are of the titular value of £40; if the financial need of an exhibitioner cannot possibly be met by this amount, the Council has power, if it sees fit and if funds are available, to award him an additional payment. Candidates must apply through the principal authority of their university. Applications for the studentship and exhibitions should reach the Senior Tutor (from whom further particulars may be obtained) by July 1, 1932.

Oxford.—Dr. Herbert H. E. Craster, fellow of All Souls College, has been elected by the curators of the Bodleian Library, to be Bodley's Librarian, subject to the approval of Convocation on Nov. 3.

Applications are invited by the Grocers Company, Grocers Hall, E.C. 2, for research scholarships in sanitary science, each of the annual value of £300, plus an allowance for expenses. The necessary form of application and information respecting the scholarships are obtainable from the clerk to the company.

The Council of the Institution of Naval Architects has made the following awards: Vickers Armstrong scholarship in naval architecture (1931) to Mr. Leonard Redshaw, of Messrs. Vickers-Armstrongs, Ltd., Barrow-in-Furness—the scholarship is of the value of £150 per annum and will be held at the University of Liverpool for three years; and the Duke of Northumberland prize (in connexion with the 1931 examinations for national higher certificates in naval architecture) to Mr. James Irwin, of the Royal Technical College, Glasgow.

Birthdays and Research Centres.

Oct. 31, 1872.—Sir **John Russell**, O.B.E., F.R.S., Director of the Rothamsted Experimental Station, Harpenden.

My work—indeed, my whole life—is so intimately bound up with Rothamsted and my colleagues there that I find it difficult to disentangle myself from them. Our general purpose is to see how far science can go in solving the problems of country life. The most fundamental problems are those associated with crop production: the management of the soil, the nutrition of the plant, the ways of dealing with destructive insects, fungi, and other pests, and the ways of utilising the crop to the fullest advantage in the service of men and of animals. These problems, therefore, form the basis of our work.

The method is to gain knowledge about the soil, the growing plant, and the animal. Experience has shown that this is incomparably better than the search for ways of overcoming particular difficulties; it gives a solid foundation of knowledge on which to develop agricultural education, advisory activities, and further research, and it has proved highly successful in adding to the resources of the countryman in his hard task of wresting a living from the soil.

Nov. 1, 1857.—Prof. John Joly, F.R.S., professor of geology and mineralogy in the University of Dublin and president of the Royal Dublin Society.

In 1914 I contributed to the *Proceedings of the Royal Dublin Society* a paper on the subject of the radioactive treatment of malignant disease and urged that uniformity of radiation would seem to be more hopeful than the use of concentrated central dosage as then generally practised. Ultimately the present extensively used ' needle method ' of application resulted, and was first put into practice by the late Dr. Walter C. Stevenson.

I have since contributed to the Royal Dublin Society suggestions for the use, in certain cases, of bi-radiant needles, namely, needles emitting rays differing unilaterally in density. Suggestions regarding deep-seated radium therapy have also been contributed to this journal as coming from our Irish Radium Institute. No problem is more urgent than this.

I have also in view considerations arising out of the surface history of the earth; the elements of which history I believe to be now well established.

Nov. 4, 1855.—Prof. F. O. Bower, F.R.S., formerly regius professor of botany in the University of Glasgow.

Since my retirement from the chair of botany in the University of Glasgow in 1925, circumstances have not been favourable for continuing detailed observation as in former years. The opportunity has, however, been used for completing " Ferns ", vol. 3, published in 1928, and a small volume on " Size and Form in Plants " in 1930. This leaves me free to draw together many facts and arguments—partly included in volumes already published, partly scattered in isolated memoirs and addresses—into a collective and revised statement relating to archegoniate plants. This will take time, and its completion—if it ever be completed—cannot be expected at any early date. All my available time will now be devoted to this end.

Nov. 5, 1876.—Prof. H. B. Fantham, professor of zoology in the University of the Witwatersrand.

The study of animal parasites has always interested me, and for some years I have been working on surveys of the parasitic and free-living Protozoa found in South Africa. The former have been considered from the morphological, biological, and experimental points of view with the view of shedding light on the evolution of pathogenicity among them. The free-living Protozoa have been studied ecologically, while making a first survey of those occurring in various types of soils and fresh waters. Human biology is also of deep interest to me. My investigations have been chiefly on cases of human heritable conditions and on racial admixture, a problem of increasing importance in South Africa, as well as in other parts of the world.

Nov. 5, 1892.—Prof. J. B. S. Haldane, Reader in Biochemistry in the University of Cambridge, head of the Genetical Department, John Innes Horticultural Institution.

I am directing and conducting research into the biochemistry of individual and specific differences, both in higher plants and bacteria. Progress in genetics demands as exact a knowledge as possible of what genes do. For example, it would appear that one gene may cause the oxidation of a particular substance, another its methylation, and so on. In some cases at least, this is done through a definite enzyme. Exact data as to the effect of genes on viability are also being collected with the view of quantitative testing of the Darwinian theory. I am developing a mathematical theory of natural selection, in which a population is represented by a point in many-dimensional space, and its trajectory under a given selective system is investigated. A number of differential, integral, and finite difference equations arising in this theory demand investigation.

Nov. 6, 1886.—Prof. I. M. Heilbron, D.S.O., F.R.S., Heath Harrison professor of organic chemistry in the University of Liverpool.

My main interests at the present time are directed towards: (*a*) the chemistry of the sterols with special reference to ergosterol and vitamin D, and (*b*) investigations relating to the occurrence, isolation, and structure of vitamin A. Under the first heading, I am attempting to elucidate the structure of the ergosterol molecule, concerning which, apart from its obvious relationship to cholesterol, little is definitely known.

Under the second section, I am continuing, in conjunction with Dr. R. A. Morton, a spectrographic and chemical investigation of vitamin A and related substances.

When time permits, I intend to extend my investigations so as to include a detailed study of the unsaponifiable matter of many animal and vegetable oils, preliminary work upon which has revealed the presence of many interesting substances.

Nov. 7, 1888.—Sir C. V. Raman, F.R.S., Palit professor of physics in the University of Calcutta, and Nobel laureate in physics, 1930, honorary secretary of the Indian Association for the Cultivation of Science, Calcutta.

During the last ten years, the attention of the workers at the Indian Association for the Cultivation of Science has been principally directed to the study of the scattering of light and its relation to the nature of radiation and the constitution of matter. Since 1928, monochromatic light has been exclusively employed and the scattered radiations have been analysed spectroscopically. This has led to a very great extension of the field of study. Probably the most important problem now under investigation is the nature of light itself. The phenomena of light-scattering make it clear that we have to atomise light and ascribe to it a specific quantum of energy and also definite values of linear and angular momentum. They also suggest that we must atomise sound, and consider it as being associated with molecular aggregates of variable size. The discovery of the phenomenon of anomalous polarisation in light-scattering has also opened up new vistas of research, which are being actively pursued. Light-scattering is also being applied to numerous physico-chemical problems.

Magnetic and magneto-optical researches are also receiving attention at the present time at Calcutta.

Societies and Academies.

London.

The Optical Society, Oct. 15.—F. Twyman and A. Harvey: The validity of the Schwarzschild relation as applied to the use of the logarithmic sector. A direct experimental test is made of the Schwarzschild relation as applied to the logarithmic sector used in conjunction with a quartz spectrograph. The relation is found to hold within the limits of the experiments, from which it follows that the length of a spectral line on the photographic plate is proportional to the logarithm of its intensity.—**F. Twyman**: The 'Spekker' photometer for ultra-violet spectrophotometry. With the original Hilger sector photometer a glass disc was supplied, with its absorption curve in the ultra-violet. This was to enable a calibration of the sector to be made on each photographic plate, and thus to avoid errors due to any assumption concerning the Schwarzschild constant. Although the original rotating sector withstood the criticisms levelled against it on the score of intermittency, there were a number of real objections to its use. The photometer described in the present paper is now made by Adam Hilger, Ltd., under the trade mark 'Spekker'. The risk that the intensity of illumination from the two aspects of the light source may be unequal is overcome by the use of two rhombs.

Paris.

Academy of Sciences, Sept. 14.—Serge Bernstein: The absolute maximum of a trigonometrical summation.—**E. Bataillon and Tchou Su**: The experimental dissociation of the male and female kinetic rhythms in the normally impregnated egg of *Bombyx*.—**Depreux**: The resistance of the air behind projectiles.—**P. R. Bohn**: The mechanism of the synthesis of fats at the expense of glucides. A comparative study of the action of *Sterigmatocystis nigra* on cultures containing dextrose and levulose, to see if there is any relation between the presence of the aldehyde and ketonic group and the formation of fat. The proportion of fat in the mycelium is higher as the concentration of the sugar increases. the change in the amount of proteins is sufficient to prevent any positive conclusions being drawn regarding the effect of substituting levulose for dextrose in the cultures.—**Raoul Lecoq**: The production of an osteo-dystrophic syndrome in the guinea-pig by disturbance of the mineral equilibrium.—**H. Quéré**: The oxidation of the alcohols by the acetic ferments, considered as a form of cell respiration. A comparison of the oxidation of ethyl, propyl, isobutyl, and isoamyl alcohols shows that the amounts of oxygen used up are approximately in inverse proportion to the molecular weight of the alcohol. The mechanism of oxidation is analogous with the mechanism of respiration.—**P. Cayrol**: The action of various halogen derivatives on alcoholic fermentation. From a study of the action of a number of halogen compounds on the process of fermentation, the conclusion is drawn that the action of the halogen atom depends on its position in the molecule: the most active halogen derivatives appear to be those which are hydrolysed at the ordinary temperature.—**Paul Wintrebert**: Sketches of *Discoglossus pictus* at the end of the blastula and at the end of the neurula stages.—**P. Delanoe**: The jackal and hedgehog reservoirs of the Moroccan spirochæte *Sp. hispanicum* var. *marocanum*. The following animals have now been proved to be carriers of the Moroccan spirochæte: porcupine, merion, fox, jackal, and hedgehog.

Sept. 21.—**Louis Lapicque**: The measurement of large chronaxies. Remarks on a note by M. Bourguignon. The author states that there is no reason to use different methods for measuring large and small chronaxies.—**Lucien Féraud**: The periodicity conditional to the neighbourhood of a point of stable equilibrium.—**A. Etévé**: Anemogirouttes. A discussion of instruments in use for the automatic control of aeroplanes.—**P. Fourmarier**: Studies of photoelectric cells as depending on the frequency of illumination.—**J. Fallou**: Measurements of the propagation constants of an aerial cable with earth return, as a function of the frequency.—**J. Bougault and J. Guillou**: Some reactions of certain barbituric derivatives (veronal, dial, gardenal, etc.). Study of the reaction of bromine and iodine in alkaline solution on some barbituric derivatives in use in medicine.—**P. Fallot**: The marginal inequalities of the limestone chain of the Rif to the north of Oued Lau.

Leningrad.

Academy of Sciences—*Comptes rendus*, No. 5, 1931.—**L. Berg**: The Black Sea sprat. A description and discussion of the synonymy of the Black Sea sprat, which is considered to be a subspecies of the Atlantic sprat and named *Spratella sprattus phalerica* (Risso).—**N. Vlodavec**: The extraction of alumina and alkalis from the nephelines and nephelinites of the Chibin Mountains. Discussion of commercial methods based on laboratory experiments.—**S. Kurbatov**: The pyrophyllite from the Tchistaya-Gora deposits in the Southern Ural. A talcum-like rock from the Tchistaya-Gora proved to contain 73·55 per cent of pyrophyllite, 23·63 per cent of quartz, 1·68 per cent of sericite, and 0·62 per cent calcium and magnium carbonates. This is the fifth known bed of pyrophyllite in Russia.

Comptes rendus, No. 6, 1931.—**V. Vernadskij**: (1) Biogeochemical studies of the phenomena of life. (2) The influence of living organisms on the isotopic mixtures of chemical elements. Both papers contain an exposition of general theoretical ideas on the subject.—**V. Vernadskij and A. Vinogradov**: Chemical composition of *Lemna* as a specific character. Analysis of four different species of *Lemna* proved that there exist definite and constant differences in chemical composition between species. Thus *L. polyrrhiza* and *L. trisulca* contain more carbon than *L. minor* and *L. gibba*, while *L. trisulca* is richer in manganese than any other species. In all Lemnaceæ the quantity of manganese is higher than that of iron.—**K. Nenadkevic**: An electro-colorimetric method for the determination of small quantities of manganese. The method is based on the electrolytic oxidation of manganese salts by ozone and oxygen *in statu nascendi*.—**V. Barovskij**: The first representative of the genus *Plateros* (Coleoptera, Lycidæ) in the Russian fauna. Description of *Plateros ussuriensis*, sp. n. from the Ussuri region.

Diary of Societies.

FRIDAY, October 30.

Association of Economic Biologists (in Botany Department, Imperial College of Science and Technology), at 11.30 A.M.—R H. Stoughton: Nuclei, Reproductive Bodies, and Cell-fusion in a Bacterium —T. H. C. Taylor: Control of the Lavuana Moth in Fiji.—Dr. P. H. Gregory: The Fusarium Bulb Rot of Narcissus.—At 2.30.—Dr. W. B. Brierley, Prof. J. W. Munro, and others: Discussion on The Training of Biologists for Economic Posts.

Royal Astronomical Society (Geophysical Discussion), at 4.30.—Isostasy. Speakers: Sir G. P. Lenox-Conyngham (who will communicate a paper by Dr. De Graaf Hunter), Prof. A. M. Davies, Dr. Harold Jeffreys, H. L P. Jolly, Prof. O. T. Jones. Chairman: Admiral H. P. Douglas.

Royal Sanitary Institute (at Town Hall, Wolverhampton), at 5.—W. Clifford: The Flow of Sewage through a Sewage Works.—Miss M. R. Baskett and Dr. H. Paul: Experiments in Reconditioning of Houses.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Specimens illustrating the Anatomy of the Pyloric Sphincter in Cases of Hypertrophic Enlargement.

North-East Coast Institution of Engineers and Shipbuilders (in Mining Institute, Newcastle-upon-Type), at 6.—Mrs. E. M. Smith-Keary: The Effect of Immersion on Propellers.

Institution of Electrical Engineers (London Students' Section), at 6.15.—G. J. Shaw and G. A. M. Hyde: The Business of Electrical Apparatus Manufacture.

Institution of Chemical Engineers (at Institution of Civil Engineers), at 6 30.—Dr. E. F. Armstrong: Hydrogenation (Lecture).

Illuminating Engineering Society (at Royal Society of Arts), at 6.30.—P. Good and others: Discussion on Some Impressions of the I.I.C. Floodlighting.

Institution of Mechanical Engineers (East Midland Branch) (at University College, Nottingham), at 6.30.—Prof. C. H. Bulleid: The Importance of Metallurgy to the Engineer

Institute of Transport (Manchester, Liverpool, and District Section) (at Adelphi Hotel, Liverpool), at 6.30.—T. E. Jones: The Horse—Its Place in the Scheme of Transport.

Institution of Mechanical Engineers (Informal Meeting), at 7.—R. Borlase Matthews and others: Discussion on Engineering in Agriculture.

Iron and Steel Institute (jointly with West of Scotland Iron and Steel Institute) (at Royal Technical College, Glasgow), at 7.15.—J. H. Andrew, W. R. Maddocks, D. Howat, and E A Fowler: The Equilibrium of Certain Non-Metallic Systems.—B Matuschka: The Solidification and Crystallisation of Steel Ingots: the Influence of the Casting Temperature and the Undercooling Capacity of the Steel.

Society of Chemical Industry (South Wales Section) (jointly with Institute of Chemistry—South Wales Section) (at Technical College, Cardiff), at 7.15.—R. D. Owen: Chemistry of Dairy Products.

Hull Association of Engineers (at Municipal Technical College, Hull), at 7.15.—J. N. Waite: Combustion and Boiler-house Efficiency.

Society of Chemical Industry (Glasgow Section) (at 39 Elmbank Crescent, Glasgow), at 7.30.—Dr John A. Cranston: The Chemist, the Community, and the Individual (Chairman's Inaugural Address).

Junior Institution of Engineers, at 7 30.—S. J. Clifton. Automatic Combustion Control.

Institute of Chemistry (Belfast Section) (at Royal Belfast Academical Institution), at 7 45.—R. G. Baskett: Recent Advances in Animal Nutrition.

Royal Aeronautical Society (at Eton College).—The Master of Sempill: Lecture.

SATURDAY, October 31.

North of England Institute of Mining and Mechanical Engineers (at Newcastle-upon-Tyne), at 2 30.—W. Cochran-Carr: Inaugural Presidential Address.—Dr. A. Crawford: The Hydrogenation of Coal.

Hull Association of Engineers (at Municipal Technical College, Hull), at 7.15.—J. N. Waite: Combustion and Boiler-house Efficiency.

MONDAY, November 2.

Royal Society of Edinburgh, at 4 30.—G. W. Tyrrell and M. A. Peacock: Petrology of Iceland Part II. The Petrology of the Acidic and Intermediate Intrusives and Extrusives, by M. A. Peacock.—Dr. Tudor Jones: The Primitive Conducting Mechanisms of the Vertebrate Heart: An Introduction to the Study of their Appearance and Development in *Lepidosiren paradoxa*.—G. W. McCrea: An X-ray Examination of *d*-Manitol and *d*-Mannose.—W. O. Kermack and W. H. McCrea: An Operational Method for the Solution of Linear Partial Differential Equations.—H. S. Ruse: On the Definition of Spatial Distance in General Relativity.

Royal Institution of Great Britain, at 5.—General Meeting.

Royal College of Surgeons of England, at 5.—C. P. G. Wakeley: Demonstration of Secondary Tumours of the Bone.

Society of Engineers (at Geological Society), at 6.—T. J. Gueritte: Esperanto in the Field of Engineering.

British Psychological Society (Education Section) (at London Day Training College), at 6.—F. Schonell: Research of Specific Disability in Spelling.

Society of Chemical Industry (Yorkshire Section) (jointly with Hull Chemical and Engineering Society and Institute of Chemistry—Leeds Area Section) (at Station Hotel, York), at 6.45.—Emulsions:—A. H. Dodd: Types of Industrial Emulsions.—J Pryce Jones: Some Aspects of Thixotropy.—Dr. A N. Mosses: One Molecule Thick.

Institution of Electrical Engineers (Mersey and North Wales (Liverpool) Centre) (at University, Liverpool), at 7.—R. M. Charley: Recent Progress in Large Transformers.—W. E. M. Ayres: The Application of the Induction Voltage Regulator.

British Kinematograph Society (in Gaumont British Theatre, Wardour Street), at 7.45.—B. Pontifex: Nickel Alkaline Storage Batteries

Society of Chemical Industry (London Section) (at Chemical Society), at 8.—Drs H. A. Auden and W. P. Joshua: The Saccharification of Wood

TUESDAY, November 3.

Royal Institution of Great Britain, at 5.15.—Prof. G. I. Finch: The Combustion of Gases in Electric Discharges (1).

North Staffordshire Institute of Mining Engineers (in North Staffordshire Technical College, Stoke-on-Trent), at 5 30.—B. R. Lawton: The Aneroid Barometer as an Aid to Improvement of Atmospheric Conditions in Deep Workings.

Zoological Society of London, at 5.30.—T. L Green: On the Pelvis of *Anura*.—C. C. John: On the Anatomy of the Head of *Sagitta* (Chætognatha).—Dr. Susan Finnegan: On a New Species of Mite of the Family Heterozerconidæ.—Prof. F. Werner: Further Notes on the Indian Mantids or Praying Insects.

Mineralogical Society (Anniversary Meeting) (at Geological Society), at 5.30.—Dr. F C. Phillips: On Crystals of Brookite, Tabular, Parallel to the Basal Plane.—Prof. T. Ito: On Scorodite from Japan.—Dr. E. S. Simpson and D. G. Murray: On a New Siderolite from Bencubbin, Western Australia.—W. Campbell Smith: On a New Meteoric Stone from Suwahib, Arabia, found by Mr. Bertram Thomas in 1930.

Institution of Civil Engineers, at 6.—Sir Cyril Reginald Sutton Kirkpatrick: Presidential Address and Presentation of Medals.

London Natural History Society (at London School of Hygiene), at 6.30.—Exhibition of Ciné Films of The Buzzard, Crabs and Camouflage, The Ant Lion, and The Swallows.

Institution of Automobile Engineers (at Royal Society of Arts), at 7 45.—B. G. Robbins: The Training of Young Automobile Engineers

Abernethian Society of St. Bartholomew's Hospital, at 8 30.—Dr. W. Langdon Brown: Dr. Robert Bridges, the Poet of Evolution (Inaugural Address).

Royal Geographical Society, at 8.30.—F. S. Smythe: The Garwhal Himalaya around Kamet

Royal Photographic Society.—T. Thorne Baker: The Spicer Dufay Colour Process.

Institution of Gas Engineers (at 28 Grosvenor Gardens).

WEDNESDAY, November 4.

Royal Society of Medicine (History of Medicine Section), at 5.—Dr. Meyerhof: A Short History of Ophthalmia during the Egyptian Campaigns of 1798-1807.

Geological Society, at 5.30.—Prof. A Holmes and Dr. H. F. Harwood: The Petrology of the Volcanic Fields East and South-East of Ruwenzori, Uganda.

Institution of Electrical Engineers (Wireless Section), at 6.—Col. A. S. Angwin: Chairman's Inaugural Address.

Institution of Heating and Ventilating Engineers (at 20 Hart Street W.C 1), at 7.—S. J Benham: Recent Developments in Cooking Apparatus.

North-East Coast Institution of Engineers and Shipbuilders (Graduate Section) (at Bolbec Hall, Newcastle-upon-Tyne), at 7.15.—D. Tagg and R. G. P. Weighton: Supercharging: its Aims and Application.

Society of Public Analysts and other Analytical Chemists (at Chemical Society), at 8.—Dr. W. R. Schoeller and H. W. Webb: The Separation of Tin from Tantalum and Niobium.—Dr. W. R. Schoeller and C Jahn: A Reliable Method for the Quantitative Separation of Titanium from Tantalum and Niobium.—Dr. J. Reilly, N. Noonan, and P. J Drumm: The Evaluation of the Menthone Content of Peppermint Oil.—D. M. Freeland: The Extraction and Estimation of Vanillin in Chocolate and Cocoa Butter.—H. R Ambler: The Direct Determination of Nitrogen in Gases.

Royal Society of Arts, at 8.30.—Sir Edward A Gait: British Research Work in India, in the Fields of History, Archæology, Philology, and Ethnology.

Royal Society of Medicine (Surgery Section), at 8.30.—G. Williams and others: Discussion on Treatment of Acute Osteomyelitis.

Institution of Gas Engineers (at 28 Grosvenor Gardens).

Royal Microscopical Society (Biological Section) (at B M.A. House).

THURSDAY, November 5.

Royal Society, at 4.30.—Sir F. Gowland Hopkins and K. A. C. Elliott: The Relation of Glutathione to Cell Respiration with Special Reference to Hepatic Tissue.—Lord Rutherford and Dr. C. D. Ellis: The Origin of γ-Rays.—Prof. A. V. Hill: Myothermic Experiments on the Frog's Gastrocnemius.—*Papers to be read in title only*:—J. L Burchnell and T W. Linnean Society of London, at 5.—Prof. F. E. Weiss: Naturalisation of *Sarracenia purpurea* in Switzerland.—H W. Pugsley: A New *Juncus* in Scotland.—A. G. Lowndes · Elutriation and some of its Applications to Biology.—Major R W. G. Hingston: Artificial Concealment Devices in Nature

Institution of Electrical Engineers, at 6.—E A. Watson: Coil Ignition Systems

Institution of Civil Engineers (Birmingham and District Association) (at Midland Institute, Birmingham), at 6 —T. J. Gueritte. The Construction of the Reinforced Concrete Bridge over the Mouth of the River Elorn between Brest and Plougastel, in Brittany.

Royal Aeronautical Society (at Royal Society of Arts), at 6 30 —H B. Irving and A. V. Stevens: Safety in Spinning

Institution of Automobile Engineers (Bristol Centre) (at Merchant Venturers' Technical College, Bristol), at 7 —B. G Robbins The Training of Young Automobile Engineers.

Institution of Electrical Engineers (Tees-Side Sub-Centre) (at Cleveland Technical Institute, Middlesbrough), at 7.

Society of Chemical Industry (Bristol Section) (at University, Bristol), at 7.30.—Drs. L. A. Jordan and W. H. J. Vernon: The Relation between Corrosion and Paint.

Chemical Society, at 8.—H. L. Riley and V. Gallafont: A Potentiometric Investigation of Electrolytic Dissociation Part I. Cadmium Halides. —Prof. G. T. Morgan and F H. Burstall: Dehydrogenation of Pyridine by Anhydrous Ferric Chloride.

Diesel Engine Users' Association (at Caxton Hall).—R B. Grey. The Elimination of Vibration.

Electrical Association for Women (at Institution of Electrical Engineers) —Dr. Elizabeth Sloan Chesser: Electricity and Health (1).

FRIDAY, November 6.

Royal Society of Medicine (Otology Section), at 10.30 a.m.—N. Patterson: The Training of an Oto-laryngologist (Presidential Address). —E. W. Williams: Treatment of Suppurative Meningitis.—Dr. D. McKenzie: Some Graphs Illustrating Otosclerosis.

Royal Society of Medicine (Laryngology Section), at 5.

Physical Society (at Imperial College of Science), at 5.—Sir Arthur Eddington: The Expanding Universe (Presidential Address).

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Specimens illustrating the Pathology of Hydrocephaly

Institution of Mechanical Engineers, at 6.—Ll. B. Atkinson: The Mechanical Aspects of Electricity (Thomas Hawksley Lecture)

Society of Chemical Industry (Manchester Section) (jointly with Manchester Sections of Society of Dyers and Colourists, Institute of Chemistry, and Chemical Section of Manchester Literary and Philosophical Society) (at College of Technology, Manchester), at 7.—Prof. H. Mark: The Significance of the New Cellulose Models (Molecular Structure) for the Technical and Dyeing Properties of the Fibre.

Institution of Electrical Engineers (Meter and Instrument Section), at 7.—F. C. Knowles: Inaugural Address.

Society of Chemical Industry (South Wales Section) (jointly witl South Wales Institute of Chemistry) (at Thomas' Cafe, Swansea), a 7.30.—Dr. Sladden: Chemistry in the Service of the Doctor.

Junior Institution of Engineers, at 7.30.—A. P. Quarrell: The Coolin of the Crude Oil Engine.

Oil and Colour Chemists' Association (Manchester Section) (a Liverpool) —N. Heaton · Modern Developments of Inorganic Pigments

Royal Photographic Society.—Pictorial Photography.

SATURDAY, November 7.

Royal Institution of Great Britain, at 3.—F. E. Yerbury: Present Day Architecture on the Continent (1) Modern Buildings in Holland.

Gilbert White Fellowship (at 6 Queen Square W.C.1), at 3 —W. B Gourlay. Plant and Animal Collecting in Chili (Lecture).

Institution of Mechanical Engineers (Graduates' Section—London (Informal Meeting), at 6 45 —Debate on: That a College Education i Desirable in the Training of a Mechanical Engineer.

North-East Coast Institution of Engineers and Shipbuilders (Tees Side Branch—Graduate Section) (at Cleveland Scientific and Technica Institution, Middlesbrough), at 7.30.—J Lang: Chairman's Address.

PUBLIC LECTURES.

FRIDAY, October 30.

British Medical Association, at 5.15 —Dr. F. J. McCann: Th Prevention of Cancer (Chadwick Lecture).

SATURDAY, October 31.

Royal Institute of British Architects, at 3.—H. B. Creswell: Th Uses of an Architect.

Horniman Museum (Forest Hill), at 3 30.—J. E. S. Dallas. A Naturalis in Western Cornwall.

MONDAY, November 2.

University of Leeds, at 5.15.—Prof. J. A. Crowther: The Life and Worl of Michael Faraday.

Royal Anthropological Institute (at University College), at 5.30.—F. J. Richards: From Pariah to Brahman in Southern India.

King's College, London, at 5.30.—Prof. H. Cloos: Problems an Methods of Structural Geology. (Succeeding Lectures on Nov. 9 and 11

University College, at 5 30 —Col. T. C. Hodson: Caste and Creed i Northern India.

National Institute of Industrial Psychology (at Royal Society o Arts), at 6.—Eric Farmer: Recent Research into the Causes o Industrial Accidents. (Succeeding Lectures on Nov. 9 and 16)

University of Leeds, at 8.—Prof F. Challenger: The Chemistry of th Friendly Microbe.

TUESDAY, November 3.

King's College, London, at 5.30.—Sir Bernard Pares · Russian History to 1861: Western Neighbours. Novgorod.

WEDNESDAY, November 4.

Royal Institute of Public Health, at 4.—L. E. Clarémont: Th Dental Health of the Citizen.

London School of Economics and Political Science, at 6.—Capt P. F. Knightley · Practical Uses of Office Machinery in the Registratio Department of a Company.

THURSDAY, November 5.

Royal Society of Medicine, at 5 —W. D. Harmer. The Relative Valu of Radio Therapy in the Treatment of Cancer in the Upper Ai Passages (Semon Lecture).

King's College, London, at 5 30.—Dr. Eveline Martin: West Afric of To-day: The Gold Coast: the Old English Forts on the Coast, an the New Inland—Kumasi.

King's College, London (at 16 Russell Square), at 5.30 —S. P. Turin Economic Conditions in Russia To-day, the Five-year Plan in U.S.S.R.

FRIDAY, November 6.

Geologists' Association (at University College), at 7.30.—Conversazione.

SATURDAY, November 7.

Mathematical Association (London Branch) (at Bedford College fo Women), at 3 —A. W. Siddons: The First Two Years of Geometry i a Secondary or Preparatory School.

Horniman Museum (Forest Hill), at 3.30.—D. Martin Roberts: London in the Age of Dr. Johnson.

ANNUAL MEETING.

October 31 to November 2.

International Society of Medical Hydrology (at American Hotel, Amsterdam) —Discussions on the Influence of Chill in the Causation o Disease, opened by Profs. Schade and van Loghem, and on Factors i Marine Treatment, opened by Prof. Möll and Dr. Haberlin.

CONFERENCE.

November 16 to 21.

International Conference on Bituminous Coal (at Carnegie Institut of Technology, Pittsburgh, U S.A.) —Subjects for discussion:—Coal a Locomotive and Steamship Fuel; Coal in the Electric and Gas Industries Competition of Coal with other Fuels in Heating Buildings; Coal in th Metallurgical Industries, Coal and its By-products in the Chemica Industries; Problems of Coking; Origin and Classification of Coals Cleaning and Preparation; Mechanism of Combustion; Pulverised Coal Relationships of Coal, Oil, and Natural Gas; Coal versus Water Power Hydrogenation and Liquefaction of Coal; Fertilisers from Coal Economics of Low Temperature Carbonisation; Storage and Weatherin of Coal, Smoke Abatement; Stream Pollution.

Industrial and Social Economics.

THE proceedings of the recent World Social and Economic Congress at Amsterdam, organised by the International Industrial Relations Association, are of the greater interest in view of the political and financial crisis which has since developed. An important paper on the principles and practice of scientific management, by Dr. H. S. Person, throws a searching light on the rationalisation movement and its applications, and discloses reasons for the apparent failure of rationalisation to effect industrial stabilisation and avert the present world-wide trade depression and unemployment. While this failure or partial failure is due in part to the misuse of rationalisation, to failure to pass on its benefits, and disregard of the principle of service, a major factor has been the limited scale on which rationalisation has been attempted. Stabilisation of a restricted area may increase the instability of the surrounding area, and complete stabilisation may be impossible owing to the impact of disturbing external forces which are outside the control of the management.

Scientific management has thus been forced continuously to extend its area of operations, and from the application of scientific principles to individual workshops has been compelled to extend them successively to the supply as well as to the production departments, to relations between workers and management, then to relations between production and markets and general administration. It is now considered necessary to apply the same principles to whole industries collectively, not merely on national but also on international lines, and it is the backward condition of many individual industrial and national units which has largely restricted the benefit to the world of the application of scientific management and rationalisation methods elsewhere.

It has already been admitted by authorities in widely differing walks of life that lack of economic statesmanship in general and of national planning in particular are the causes of depression, and the Macmillan Report asserted that an era of conscious and deliberate management must succeed the era of undirected natural evolution and haphazard development which has characterised the past. The recognition that economics acknowledges no frontiers prepares the way for an era of co-operation in which the disturbing intensive competition in basic necessities on a world scale is eliminated.

The keynote of the new era, as suggested by Dr. Lewis Lorwin, is to be economic planning, and this should be distinguished from both rationalisation and scientific management, of which it is a development. Although rationalisation implies a wide application of scientific methods and increased productivity, and has sometimes made for low prices, high wages, and mass prosperity, it has more often been used to maintain levels of prices out of proportion to decreasing costs of production. Experience shows, further, that combination for business purposes alone tends to restrict production and to maintain profitable price levels. What is now contemplated goes far beyond such conceptions and involves planning national and world development to give maximum satisfaction of the economic and the social needs of a people within a definite period. Essentially it attempts to correlate production and distribution on a world scale. It is offering new conceptions of economic life and methods of promoting a steady growth in standards of living.

Various attempts at social-economic planning have already been made. The voluntary business type is familiar and its limitations have led to the emergence of a social-progressive type of planning, which is that apparently contemplated by the Macmillan Committee. Such planning implies that economic leadership is not a monopoly of the business man, and involves a measure of governmental authority. It is a further break from the policy of *laissez faire*, and is in line neither with the traditions of free trade nor of nationalistic economic policies which since the War have developed protective tariffs to a height entirely disproportionate with economic need and rational development of industry and trade.

Scientific workers will welcome this movement as promising to relate administration and policy to the basic facts of the industrial, economic, and social system, and to liberate them from their bondage to political prejudices. Fundamentally, economic and social planning of national or industrial life involves research on the various factors involved before the successive stages of standardisation, control, stabilisation, co-operation, and planned development, can be realised, leading us to scientific management on a world scale. It involves the balancing of opposing group interests on the basis of ascertained facts and not on the self-valuation of the groups concerned.

Dr. Lorwin considers that there is nothing in the present situation to justify the easy belief that the depression will right itself without conscious effort, that the world need not be troubled with the spectre of its recurrence, or that the rapid economic changes which have persisted since the War will come to an abrupt end. On the contrary, as emphasised by Mary van Kleeck, vice-president of the International Industrial Relations Association, in summarising the discussions at the final session, the security of civilisation demands the exercise of the most expert intelligence which the world's intellectual and technical resources can bring to bear on the common world task of maintaining and raising the standards of living of all people. This involves not merely the handling of the immediate critical problems but also the direction of the resources of intelligence towards the constructive upbuilding of social economic life. Statistical research must indicate the ways in which the world's productive capacity, so greatly increased by technical developments in the last twenty years, can be utilised to raise the standards of living.

Social-economic planning is thus no simple conception. Mary van Kleeck suggested that a world research centre is needed to co-ordinate technical effort, to secure uniformity in statistics bearing upon economic planning, develop greater precision in the methods of economic and social research, and to focus investigations upon practice, in the same way that scientific discoveries are applied in engineering and other industries.

Such planning postulates an adventurous spirit, a greater faith in the possibilities of life, a sense of social and ethical values; and holds out to man, through the synthesis of science and vision, a prospect of ordered evolution. As Dr. Lorwin points out, it is based on a philosophical faith in the power of man to promote orderly economic and social change through scientific research and constructive imagination.

History of Alchemy.

Entstehung und Ausbreitung der Alchemie. Von Prof. Dr. Edmund O. von Lippmann. Band 2: *Ein Lese- und Nachschlage-Buch.* Pp. vii + 257. (Berlin: Julius Springer, 1931.) 26·60 gold marks.

OF all works on the history of alchemy and early chemistry, that to which reference is made most frequently and with most confidence is Prof. E. O. von Lippmann's "Entstehung und Ausbreitung der Alchemie". Published in 1919, it immediately became indispensable to every student of the subject, and in the twelve years that have elapsed since its first appearance, its reputation as a masterpiece of wide learning and careful scholarship has become thoroughly established. Those twelve years have, however, seen the publication of much research upon the history of chemistry and alchemy—an amount probably greater than in any previous period of the same length—so that we must count ourselves fortunate in the fact that Prof. von Lippmann's seventy odd years have apparently in no degree diminished his prodigious activity.

This second volume is supplementary to the first. The articles in it are arranged alphabetically, as in an encyclopædia, and since the book is provided with three excellent indexes, reference to any particular topic can be made quickly and exhaustively. Some idea of the mass of new information that the author has collected may be gained from the fact that this supplementary volume is more than one-third of the size of the first, running to 257 pages. The sources of this abundant new matter are fully indicated, and Prof. von Lippmann has enriched the whole with that careful criticism and sound judgment so characteristic of all his historical writings.

To do justice to the book, a detailed review of considerable length would be necessary, but some of the most interesting features may be considered here. The problem of alchemy in China has attracted a good deal of attention lately, some authorities having suggested that alchemy was practised in that country centuries before the Christian era. If this suggestion were to be confirmed, it would be necessary fundamentally to revise our present views on the origin of alchemy, though on other grounds these would seem to be well established in broad outline, if not in detail. Prof. von Lippmann mentions the work of O. S. Johnson, who regards Chinese alchemy as an indigenous growth arising from the system of Taoism, and the more recent article of Davis and Lu-Ch'iang Wu, who suggest that alchemy may have flourished in China so early as the second century B.C. He himself agrees with Laufer that alchemy is an entirely foreign element in Chinese thought; but while Laufer believes that alchemy appeared in China in the second century B.C., " when China was actually flooded by an invasion of influences rushing on from the West ", von Lippmann, on the contrary, is of the opinion that the introduction was made by the Arabs towards the beginning of the ninth century A.D. This appears to be the more likely, inasmuch as Chinese alchemical writings are said to be clearly affiliated to the early form of Arabic alchemy, in which the Greek influence was more fully apparent than it became later. Prof. von Lippmann would regard alchemical passages in Chinese works definitely earlier than the ninth century A.D. as skilful interpolations of a considerably more recent date.

On the discovery of alcohol, the author finds no reason to alter his previous conclusion: that is, that alcohol was first obtained by distillation in southern Italy in the twelfth century. He regards as erroneous the old tradition that alcohol was first prepared by the Arabs—a tradition that certainly finds no support from any Arabic alchemical treatises hitherto studied.

The perplexing problem of Jabir or Geber has undergone yet a further transformation through the work of Kraus, Schaeder, and Husain Hamdani. From a study of certain Arabic works of Jabir published by the reviewer, these scholars conclude that while the books in question were undoubtedly written by a single author, they must be assigned to the end of the ninth century or the beginning of the tenth. An earlier date is impossible, since the books are steeped in the doctrines of the Isma'ilite sect, which arose in the latter half of the ninth century. The conclusion is supported by the fact that the author uses terms of ophthalmic medicine which did not appear in Arabic literature before A.D. 860. The provisional identification of Jabir's father with the Abbasid agent Hayyan, who lived at the beginning of the eighth century, must consequently be regarded as untenable, and we are still left in ignorance of the life of the greatest chemist of Islam.

Prof. von Lippmann would make the discovery of the mineral acids contemporaneous with the improvements in distillation that led to the discovery of alcohol in the twelfth century. On general grounds, however, this late date seems improbable, since alum and blue and green vitriols were well known in earlier times and must have been heated occasionally in such a way that Nordhausen acid was obtained. There is, moreover, an Arabic work ascribed to Jabir (" The Chest of Wisdom ") in which the preparation of nitric acid is clearly described, though—as is so often the case—the work may not be authentic. Later Arab chemists were certainly well acquainted with nitric acid, which they called " parting-water " on account of its use in separating gold from silver.

Among the etymologies mentioned by von Lippmann are several of interest. Thus ' sory ', a mineral name of frequent occurrence, is derived from the Egyptian ' se-ur ', the great salt; ' kassíteron ', the Greek name for tin, probably comes from ' kassitira ', meaning ' from the land of the Kassi ' or Kassites, a people first mentioned about 2100 B.C.;

while the suggested derivation of indigo from the Egyptian 'n-tinkon' or 'dinkon' has not been confirmed.

The extraction of zinc probably arose in Persia, where it was certainly practised towards the end of the sixth century A.D. There was, however, confusion of this metal with tin for nearly another thousand years, though Boyle always clearly distinguished between spelter (zinc) and pewter (here tin or an alloy of tin and lead). The extraction of zinc was introduced into England by Lawson, about 1700, who had learnt the process in China, and the chief centre of production was Bristol. Zinc oxide was used in the treatment of disease so early as 1150.

Antimonium, as the name of antimony sulphide, is derived from the Greek ἀνθεμώνιον, and may be explained by the characteristic appearance of the naturally occurring crystalline mineral. The element itself has been known for at least 4500 years, since a large antimony bowl of the time of King Gudea (about 2600 B.C.) has recently been discovered.

Such are a few samples of the interesting fare that Prof. von Lippmann sets before us. So far as we have been able to ascertain, very little has escaped him, however obscure the source, and his book is bound to prove of the utmost possible value to historians of chemistry. We feel that perhaps he has not made as much use as he might have done of Dr. Campbell Thompson's investigations into the chemistry of the ancient Assyrians, and that more attention might have been paid to alchemical theories as distinct from facts; but these are minor points that in no way detract from the excellence of a wholly admirable book.

E. J. Holmyard.

The Prehistoric Colonists of Yorkshire and their Economics.

Early Man in North-East Yorkshire. By Frank Elgee. Pp. xvi + 259 + 30 plates. (York: The Author, Shirley House, Commondale, 1930.) 25*s*. 9*d*.

A MINUTE field study of a quite small area often paves the way not only to a vivid realisation of the life of our forerunners in the region studied, but also to the solution of problems of much wider scope. Mr. Elgee has not only tramped the moorlands and vales of north-eastern Yorkshire, closely scrutinising the humblest traces left there by prehistoric man, but he has also ransacked the obscure records left by early antiquarians. The results of this labour of love, embodied in the eminently readable and richly illustrated volume before us, will be welcomed both by the specialist, as a solid contribution to prehistory, and by the layman, as a fascinating picture of early life in a delightfully scenic background.

The first inhabitants of the region would be the makers of the mysterious pygmy flints, many of which the author has himself detected. They would have been followed by wielders of stone axes, but it may be doubted whether these can, as here suggested, be separated from the builders of long-barrows and Beaker folk, who certainly used such tools. A rectangular cross-section in celts of stones other than flint does not necessarily betoken Scandinavian influence, since fine-grained rocks are often shaped by sawing. The long-barrow builders in any event represent an influx from the west; for Mr. Elgee successfully defends the connexion of the Yorkshire monuments with those of western England against Kendrick's attacks, though he is not attracted by my suggestion of a wooden chamber under such barrows, and is convinced of the deliberate intention of the incinerations noted by Greenwell. The arrival of these colonists from the west did not long anticipate the advent of invaders from the east, here divided into two groups—Beaker folk and battle-axe folk of more northern affinities. In this connexion a remarkable (?) copper double-axe of pure Cretan type from Whitby is here described, though its ancestry must lie in the south, and it is the prototype rather than the descendant of the Danish stone axes with which it is justly compared. Both groups settled in north-eastern Yorkshire, in only small numbers in comparison with the intensive occupation of the Wolds, and avoided the bleak moorlands altogether, as had the long-barrow builders, with whom the easterners eventually amalgamated.

In the later Bronze Age, on the other hand, cinerary urns are more abundant in the north-east than in the south, and spread right into the moorland wastes. Mr. Elgee argues that the vessels were made by descendants of the earlier Bronze Age population, and that the cinerary urn was developed out of the food vessel in Yorkshire itself. The spread of the autochthonous population on to the inhospitable moors would result from the pressure of fresh invaders, characterised by new types of bronzes, who by virtue of their superior weapons would have been able to occupy the more fertile wolds and vales. These intruders would be Peake's sword-bearers and the 'Hallstadt' folk

(Hallstatt is thus misspelt throughout the book) whose settlement at Scarborough has recently been discovered. To the same people are attributed the lake-dwellings in Holderness and near Pickering, two of which have yielded bronzes of the foreign types, though most of the pottery has been called Romano-British.

In any event, our author establishes a sufficient discrepancy between the distribution of the 'native' cinerary urns and that of the 'foreign' bronzes to confirm Crawford's view that the latter were introduced by Continental invaders. The last wave of intruders before the Romans was the people of La Tène, a culture responsible for the famous chariot burials. This people can be with some confidence identified with the Parisii of Ptolemy. Their neighbours, the Brigantes, must then have been descended from the sword-bearers, and Mr. Elgee advances an ingenious argument to prove that these spoke a Goidelic language.

Thus Mr. Elgee's researches seem to have cleared up the ethnological history of his district in a manner calculated to throw light on the general problems of British archæology. But even more interesting is the fresh evidence on primitive economics here collected. The use of Whitby jet in prehistoric times is critically and cautiously studied. It does not afford any support for the thesis that 'megalith-builders' came to Yorkshire to exploit the deposits of this commodity. The distribution of the monuments seems to be bound up with that of suitable pasture-land.

Then our author has identified on the moors the settlements of the late Bronze Age people, their fields and their routes. The major barrows covering cinerary urns are found to be strung out along natural ways exactly as Sophus Müller found in Denmark. The lines of large howes link up regular cemeteries of smaller barrows which, though they seldom yield datable objects, must be regarded as the graves of commoners of the same culture. In the immediate vicinity of the cemeteries Mr. Elgee finds stony areas, sometimes defended by banks and ditches, which he plausibly interprets as the settlements of the barrow-builders; and near by are irregular enclosures comparable to the cultivation plots found near hut-circles on Dartmoor. Such big stones have been left in the plots that they must have been tilled with the hoe rather than the plough. Thus a peculiar system of rural economy which can be paralleled on other moorlands in the British Isles is logically attached to a specific phase of the Bronze Age culture, and its cultural age, recently called in question, is convincingly established. We say 'cultural age' advisedly, since it is here very properly admitted that many barrows with cinerary urns are posterior to the advent of the Hallstatt and even of the La Tène invaders.

Less convincing is the theory borrowed from Mortimer, that the barrows are laid out to represent constellations, thus indicating star worship. Prehistoric man did not view the cemeteries from an aeroplane, and from the ground can scarcely have seen the similarity of a barrow-cluster to the Plough that we can observe on a drawn plan.

V. GORDON CHILDE.

The Behaviour of Young Children.

Intellectual Growth in Young Children. By Susan Isaacs. With an Appendix on Children's "Why" Questions, by Nathan Isaacs. Pp. xi + 370. (London: George Routledge and Sons, Ltd., 1930.) 12*s.* 6*d.* net.

THIS book, the first instalment of a three-volume work on the behaviour of young children, is a valuable contribution to a vitally important subject. The last few decades have seen the emancipation of psychology from the dead hand of traditional philosophical thinking: the last few years, the partial emancipation of child study from the tyranny of outworn ideas. Dr. Susan Isaacs has based this volume on the records of work carried on under her direction at the Malting House School for young children at Cambridge in the years 1924–27. The school consisted of a group of intelligent children ranging at the outset from 2½ to 5 years of age. Its aim (so far as intellectual development is concerned) was to stimulate the active inquiry of the children themselves by bringing within their immediate experience every range of fact to which their interests reached out. This was indeed a formidable undertaking, but one of real importance and profound interest.

Indications are not lacking that the intelligent child is capable of taking a scientific interest in the external world, even in the so-called pre-school period. It becomes, then, a matter of great urgency to obtain accurate and full records: these records must represent first-hand observations by skilled and unprejudiced inquirers. How else can a start be made on solving the problem of successfully fostering the scientific interests of the young child?

The intensive study of the behaviour of young children is also of significance from the point of view of pure science. The disastrous effects of allowing untested *a priori* ideas to dominate psychology can only be counteracted by the careful study of human beings from the cradle to the grave, in which facts are the basis for cautious inductions and tentatively constructed concepts. It may also well be the case that full and deep knowledge of the mental functioning of human beings depends fundamentally on knowledge of this functioning in the young.

The importance of the problem of behaviour to be attacked in this trilogy needs no stressing, but it may be useful to point out that the method of the inquiry will repay the attention of the methodologist. Here we have a domain where even careful observations and simple experiments are comparatively few in number. In this book the records are presented dispassionately, with a detailed account of the conditions under which they were made. One of the difficulties has evidently been how to select from so great a wealth of material, without falling into the errors of those older psychologists who made their particular psychological generalisations first and selected their instances after. Particularly interesting in this connexion is the inclusion of the full records for four distinct weeks in the life of the school. Here there is no selection of data: a fair sample of the available data is recorded impartially for the use of the students of the subject, in accordance with the best canons of scientific method.

Side by side with the collection of scrupulously careful first-hand observations are certain sections in which the author gives an account of the theoretical views to which she has thereby been led. As a specially interesting example of this, we may cite the work on the biological interests of the young child. Some of this work was originally published in the *Forum of Education* and so is known to those who are interested in suggestions which scientific theorising has to offer as to the optimal education of the young child. In its more complete form, it should attract the attention of the professional educationist and also of the parent who seeks to assist his child to a fundamentally sound conception of living things. The records deal with a period of three years and range from the growing of mustard seed to the care of tortoises, worms, tadpoles, salamanders, and lizards, from the observation by the children of pregnant and suckling mice to the dissection of a crab, a toad, and a mouse.

Just how important in the emotional and intellectual development of the individual this early acquaintance with the essential facts of life, death, and reproduction may prove is still, I take it, an open question. However, according to current psychological theories, the probability is that it has considerable value. In the further development in the future of this problem of educational technique, this clear-cut contribution must prove of value. The actual records are here for all to use who care to do so. There are, besides, inductions from these records as to the conditions which should be satisfied if we are to make (p. 164) " a positive educational use of the child's impulses, so that they shall be fertile in skill and imaginative understanding and lead out of themselves to the world of objective knowledge and common human purpose ".

Mention should also be made of appendices from the pen of Mr. N. Isaacs on children's 'why' questions, an essay of great interest and high epistemological worth, and his short article on " Education and Science ", originally published in NATURE for July 23, 1927, p. 105, which is here reprinted.

Dr. Isaacs' book is destined to take its place among the classics on the behaviour of young children. Educationists, psychologists, and intelligent parents will await with lively interest and considerable impatience the second volume, which will deal with the social development of young children, and the third, which will contain individual histories of some of the child collaborators, to whom the author has dedicated the work.

JEAN AYLING.

Short Reviews.

Fifth International Botanical Congress, Cambridge, 16–23 August, 1930. Report of Proceedings. Edited for the Executive Committee by F. T. Brooks and T. F. Chipp. Pp. xiv + 680. (Cambridge: At the University Press, 1931.) 21*s.* net.

THE publication of the Report of the Fifth International Botanical Congress within little more than a year after the close of the meeting reflects credit on all concerned. In the preface to the volume, the president, Prof. A. C. Seward, pays a tribute to the efficiency of the two honorary secretaries and editors and to the memory of one, Dr. T. F. Chipp, who died while the book was passing through the press.

The Report records the history of the Congress from its inception in 1926, the personnel of the officers and of the executive and sectional committees, and also the names of delegates, representatives, and members. The detailed programme of the meetings, excursions, and social activities will recall to those who participated the interests and experiences of a crowded but enjoyable week in Cambridge in August 1930. A volume of abstracts of communications provided by authors was prepared for use during the Congress; these have been incorporated, with some additions, in the present report, and the recorders of sections have also supplied a précis of the various discussions. A very full report of the work of the Congress thus becomes available, and will be valued not only by members, but also by botanists generally as providing expression of opinion by experts on subjects of current interest. An index of authors of papers and speakers in discussions facilitates reference. The *compte rendu* of the discussions in the subsection appointed to revise the rules of botanical nomenclature, prepared by the *rapporteur général*, Dr. John Briquet, will be of special interest to many botanists.

A photograph of the president forms a frontispiece to the volume, and one of the executive committee and officers is placed at the end. The book is clearly printed and of attractive appearance; a word of thanks is due to the Cambridge University Press for its share in this production.

Acoustics: a Text on Theory and Applications. By Prof. G. W. Stewart and Prof. R. B. Lindsay. Pp. ix+358. (London: Chapman and Hall, Ltd., 1931.) 25*s.* net.

THE revitalisation of the subject of acoustics brought about by applications of the thermionic valve is reflected in all the newer books on the subject. The present volume, based upon lectures in a graduate course in electrical communications given at Yale University by Prof. Stewart, who is known for his pioneer work on acoustical filters, is no exception. So good is the book that one can merely note two minor defects, the omission of authors' names from the index and the rather too comprehensive title.

Since the plan followed is to give only as much of general acoustical theory as is necessary for the treatment of the topics selected, omitting such subjects as vibrating strings and bars, the title "Theory of Applied Acoustics" would perhaps have expressed better the scope of the book. Needless overlapping with standard general works on sound is avoided and the space so saved is used to give remarkably lucid expositions of modern developments. Of necessity a good deal of difficult mathematics has to be used, but one feels that the mathematics has been written in a physical laboratory, as, for example, on p. 22, where in the midst of a derivation of the general wave equation a pause is made to examine the actual numerical values of the quantities represented by the symbols.

The book is so written that the treatment of many particular subjects can be read without further reference to other pages. Many readers will be thankful for such foresight as that shown on pp. 55-56, where the authors take care to explain not only their own use of the term 'acoustic impedance' but also the three other different uses in the literature. The book can be heartily recommended to all interested in modern acoustics.

W. H. G.

Handbook of Cornish Geology. By E. H. Davison. Second edition. Pp. 114+4 plates. (Truro: Oscar Blackford, 1930.) 6*s.*

SINCE the first edition of this excellent little book was issued, in 1926, many investigations of the mineral veins and igneous rocks of Cornwall have been made, largely as a result of the work and influence of the author and of Dr. A. Brammall. Mr. Davison is well known as an authority on the Cornish lodes, and Dr. Brammall's unsurpassed petrological work on Dartmoor has stimulated his colleagues and students to apply his methods to the Cornish granites. In consequence, though only five years have elapsed, the second edition marks a very considerable advance on the first. Many parts of the chapters on contact metamorphism, volatile constituents, and lodes have been rewritten, and a new chapter has been added on china clay.

As an outline of the geology and mineralisation of one of the most interesting of English counties the book should be widely welcomed by teachers and students of petrology and of mining and general geology. It is simple and lucid in style, and clearly and effectively illustrated with maps, sections, and photographs. There is certainly no better guide to the visitor who takes an amateur interest in his geological surroundings. Brief descriptions of localities of geological interest are given, and of the chief mines and their minerals. It is recorded that, although most of the mines are at present perforce closed down, specimens worth collecting can usually be found on the waste heaps. A bibliography is added of the Survey maps and memoirs and of the chief papers published since 1906 relating to the district.

The book can be warmly recommended to all who are interested in the geology and economics of Cornwall.

Physical Metallurgy Laboratory Manual. By Dr. Norman E. Woldman. Pp. v+259. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 17*s.* 6*d.* net.

THIS manual is intended to give the student of metallography a series of exercises with the object of familiarising him with the structure of the most usual metals and alloys. The theory of the subject must be studied elsewhere, and stress is here laid on the practical methods of metallographic examination. The book contains a very large number of illustrations, mostly photomicrographs, and detailed directions for the development of each structure are given. The taking of heating and cooling curves and the determination of the effects of heat treatment on the structure of steel are also described. A short section on the subject of X-rays is useful so far as the detection of blowholes and cracks by that means is concerned, but the pictures of crystal structure obtained by the passage of X-rays through metals would be unintelligible without further explanation than is given here. The use of high magnifications is illustrated by some of the well-known photographs of Lucas, but a warning that only investigators of quite exceptional experimental skill can obtain such results at a magnification of several thousand diameters would not have been out of place. Most of the photographs are of very satisfactory quality, and the book will be found useful for reference, even by those who do not wish to work through its exercises.

The Advancement of Botany.*

By Prof. T. G. HILL.

DOUBTLESS it is a coincidence that the year 1831 marks not only the founding of the British Association but also, so far as a date can mark, the beginning of a threefold epoch in botany: the search for a natural system of classification; the emergence of morphology as a study separate from taxonomy; and the development of physiology.

In the first, Britain gave a full share; but in morphology and physiology, on the other hand, the tale of British activity is dismal indeed: against a battalion of Continental workers we could barely range a section, and British work caused only a ripple on the botanical surface. But there is one exception: the brilliant generalisations of Charles Darwin.

MORPHOLOGY.

In 1831, morphology for the most part had relation to the phanerogams only; the structure and life history of no plant was completely known; the fields of the vascular cryptogams, the bryophytes, and the thallophytes were almost untrodden. It is not surprising, therefore, that when ontogeny came into being the trickle of investigations fast developed into a flood, and for this the greatest honour is due to Schleiden, Nägeli, von Mohl, and Hofmeister, for they showed the way and contributed the most.

A welter of facts was discovered, many of which, especially those relating to the Thallophyta, had to await the arrival of a new technique, that of cytology, before co-ordination was possible; but for the Muscineæ, the vascular cryptogams and the angiosperms, the times produced the man whose patient and detailed work, directed by a keen intellect, gave cosmos to morphological inquiry. I refer to Hofmeister, one of the greatest botanists of all time. He first traced the development of the sexual organs and of the embryo. He was the first correctly to interpret heterospory: he discovered the alternation of generations. Nowadays, alternation of generations is accepted as a matter of course, but when it is realised that Hofmeister was working it out, almost cell for cell, more than eighty years ago without the aid of the microtome and of cytological technique, as we know it, it will be appreciated how great was his work.

Although many contributed to anatomical knowledge, the great advances were associated with the names of relatively few men. Of these, Schleiden and Schwann, the zoologist, are the first to be commemorated since they laid the foundation of the scientific study of anatomy in their theory of the cell, which enabled others, especially von Mohl and Nägeli, to build a knowledge of the anatomy of plants on a sound basis. Von Mohl discriminated the tissue elements and traced the course of the vascular system. He was the first accurately to trace the development of vessels and gave the first correct account of stomates. His observations on periderm and cambial activity are of first-rate importance.

Nageli made several well-known anatomical investigations. His investigations on the cell wall and on the starch grain are classical: the recognition of the cell wall as a product of protoplasmic activity, growth by intussusception and the occurrence of granulose and amylose in the starch grain, need only be mentioned. The results he obtained by the use of polarised light were as important as those of Sponsler and others by the use of X-rays in our own times.

In the earlier study of cytology, von Mohl and Nägeli were the pioneers. Von Mohl was the first to see cell division. Later, he studied the 'mucilage' described by Schleiden in 1838; he recognised it as a distinct component of the cell and gave it its present name, protoplasm. He described the primordial utricle and realised that the streaming movements of the cytoplasm were independent of the cell sap. Further, von Mohl perceived that the matrix of the chloroplast was protoplasmic.

Nägeli more carefully observed the nucleus and appreciated the facts of cell division more truly; and in this he was the first to recognise that the nucleus is the starting-point. With the passing of time it was recognised that the protoplasm of the plant and of the animal is identical and that it is the basis of life, a conclusion to which Payen, Cohn, and Max Schulze contributed much.

The improvement of microscopical technique led to great discoveries in the details of nuclear division. In this the work of Strasburger is outstanding, and to him is due the main credit of firmly establishing that aspect of botany now called cytology. The contributions of Fleming and of Schmitz must, however, not be overlooked, nor those of Guignard, who, unfortunately, prejudiced his own work by his description of structures which had no existence.

PHYSIOLOGY.

Our knowledge of osmotic phenomena is founded on Dutrochet's studies (1827) on differential diffusion through a colloidal membrane. Graham showed (1854) that the rate of this diffusion depends, *inter alia*, on the nature of the membrane. This led to Traube's discovery of the so-called artificial cell produced by dropping a crystal of copper acetate into a solution of potassium ferrocyanide. This observation was used by Pfeffer (1877), who supported the membrane of copper ferrocyanide in the wall of a porous pot and with it made many highly important observations. Thus was born a branch of physical chemistry, and one of the first results was van't Hoff's theory of solutions. At this time de Vries also was busy on the problem and contributed a great deal to it.

---

* From the presidential address to Section K (Botany) of the British Association in London on Sept 28.

Hales, Priestley, Senebier, Ingen Housz, and de Saussure were the pioneers in the study of carbon assimilation, with the result that the more obvious facts were known before 1831. Of these men, de Saussure was the greatest: he was the first to strike a balance which indicated the unity of the photosynthetic quotient, and to show that water and salts, as well as carbon dioxide, are essential for the nutrition of the green plant. His work, however, naturally did not convince the upholders of the humus theory; the problem was settled beyond dispute by Boussingault, who, in 1851, introduced the method of water culture.

Dutrochet (1837) correlated carbon assimilation with chlorophyll and was the first to use the 'bubbling method', a method adopted and improved by Sachs and used by him in quantitative experiments.

Von Mohl (1851) considered that a carbohydrate was formed from the carbon dioxide, but it was Sachs who proved that the starch grains in the leaf were produced from carbon dioxide. Sachs considered that starch was the first product of carbon assimilation; it was not until some years later (1885) that Meyer showed that there were sugar leaves as well as starch leaves and thus indicated that sugar preceded starch in the process.

Turning to the pigments associated with photosynthesis, Grew was the first to suggest that chlorophyll, using the word in its loose sense, was made up of more than one pigment, but to Stokes (1864) is due the credit of making the first real advance; he demonstrated the presence of two green and two yellow pigments. The methods of separation of the mixed pigments were in time refined and culminated in the work of Tswett (1906), who, by his chromatographic method, separated two chlorophylls and five carotinoids, of which one was carotin and the others xanthophyll.

Many years were to elapse before the chemical constitution of chlorophyll was to be elucidated, but Hoppe-Seyler was the first to make the significant discovery, in 1879, that there is a chemical relationship between the green pigment of the plant and the hæmoglobin of blood. The formaldehyde hypothesis was originated by Butlerow (1861) and developed by Baeyer (1870).

Before 1831 certain fundamental facts of respiration were known: Ingen Housz had shown that the plant absorbed oxygen and evolved carbon dioxide, and de Saussure had discovered that a continuous supply of oxygen was necessary for the life of the ordinary plant, that the more vigorous the organ the greater was the amount of oxygen consumed. Dutrochet (1837) confirmed the work of de Saussure and showed that responses to stimulation are not made in the absence of oxygen. He distinguished between the evolution of oxygen in carbon assimilation and the evolution of carbon dioxide in respiration, which facts were confused by many subsequent workers.

The reasons for our deficiencies during this epoch are patent. In the first place, the classical traditions of our old universities dominated teaching, with the result that the approach to biology was, in the main, through medicine. Other reasons lie in the facts that the period was one of exploration, expansion, and development of the Empire, which meant an inflow of great numbers of plants for identification, and the labourers were few. Finally, the systematists did not entirely favour the new movement and, if not actively antagonistic, they looked upon it with amused tolerance.

THE RENAISSANCE OF BOTANY IN BRITAIN.

The botanical renaissance in Great Britain began about 1875 and it happened in the Royal College of Science. The credit for it is due to Thiselton-Dyer, who, as Huxley's demonstrator, instituted and conducted the first laboratory classes in botany. University College, London, immediately followed. At Cambridge was Sydney Howard Vines.

In 1882 in all branches of botany there were masses of well-ascertained facts; the principles appeared to be settled and the problems formulated. Some aspects, such as anatomy, were in an advanced stage and were developing in various directions; other aspects, physiology, for example, were relatively backward.

In Germany especially, causal morphology was more dominant, in which development von Goebel played a pre-eminent part. His work and his teaching on the influence of the environment on the configuration of plants cannot be too highly appraised; he with Wiesner, Haberlandt, Stahl, Bonnier, and other pioneers stripped morphology of its formalism and revealed the plasticity of the plant.

Of the lower groups I shall say but little; one name, however, leaps to mind, that of Klebs, whose work on the conditions governing the reproduction of the green Algæ is classical. In mycology, Marshall Ward laid the foundation of the modern British school. Of a later date, Blakeslee's discovery of heterothallism was of the greatest importance and led to far-reaching results.

A great contribution to our knowledge during this period was given by the palæontologists. Stur and Williamson recognised the occurrence of fern and gymnosperm characters in certain fossil plants, and with the increase of evidence a separate phylum was recognised and named Cycadofilices by Potonié in 1899. Later, in 1906, Oliver and Scott made known their observations on the seed-like structures attached to the fronds of *Lyginodendron*. Passing on to the gymnosperms, the work of Strasburger and others was continued and many gaps in our knowledge were filled; but of all these investigations the most sensational was the discovery in 1896 of the motile sperms in *Ginkgo* and *Cycas revoluta* by Hirasé and Ikeno respectively. Mention also must be made of Wieland's important work on Cycadeoidea and other fossil cycads.

This progress was accompanied by that of detailed cytology, which immediately reacted to the conception of Strasburger and Weismann that the nucleus is the bearer of heredital qualities (1884). The reduction in the number of chromosomes was discovered in the parasitic worm *Ascaris* by van Beneden in 1883; the next year Strasburger observed it in the Angiosperms, and this was followed by similar observations by Overton and by Farmer in other groups. Thus was initiated a period of intense cytological study.

The condition of anatomy in 1882 is shown by De Bary's "Comparative Anatomy of the Phanerogams and Ferns": the fundamental facts were well ascertained and the application of those facts determined the direction of increasing knowledge. In Germany the trend, initiated by Radlkofer, was taxonomic, and Solereder took the leading part; in Austria, Haberlandt developed physiological anatomy, whilst in France the drifts were various. The study of purely descriptive anatomy was continued by Hovelacque, for example; Sauvageau, Costantin, and others studied structure in relation to environment, and van Tieghem was the father of stelar theories. In Britain the main morphological interest was phylogeny and this gave the bias to anatomical study. Its principles were first applied by Williamson and Scott in their studies of the fossil plants of the coal measures.

In 1883 van Tieghem and Duliot published their theory of the stele. Their deductive conclusions were not checked by ontogenetic studies, with the result that their theories were discredited soon after the intensive investigations on vascular anatomy were begun in Great Britain. In remembering those who contributed most to this aspect of vascular anatomy, Gwynne-Vaughan comes first, not only on account of his sustained work, but also for the fact that he recognised and demonstrated the importance of the leaf trace.

In the year 1900 came the independent discovery of Mendel and the confirmation of his work by de Vries, Correns, and Tschermak. The effect was immediate; for the first time genetics had definite laws which clarified many problems and disclosed others. It is doubtful if any other botanical work caused such an outburst of activity over so wide a field: a period of intense plant breeding set in; the transmission of colour factors stimulated the investigation of the flavones and other petal pigments and also the distribution of oxidases; and a new field of vast area was opened to the cytologist.

This period is remarkable also in that it saw the growth of ecology. The first ecologist was Humboldt, who was the first to realise the units of vegetation and to essay their ordering (1805). His system, however, was unsound. Interest in the subject was resuscitated by Grisebach in 1872.

Ecological study now became very active: in France, Bonnier was at work on the influence of edaphic factors on plant form and Flahault on vegetation surveys. In Belgium, Massart was studying littoral vegetation (1893), and in Switzerland there was Schröter. A few years later saw the entry of the American vanguard—Clements, Cowles, Harshberger, Livingstone, and Pound, and in New Zealand Cockayne followed his lonely bent (1901). Robert Smith was the pioneer in Great Britain: in 1898 he published his observations on the plant associations of the Tay Basin, and this was succeeded by various other communications. He was followed by his brother, W. G. Smith, Moss, Rankin, Lewis, Tansley, Yapp, Oliver, and others.

Another noteworthy series of observations of this period was those on the ascent of sap. Strasburger's experiments pushed home the idea that the phenomenon was entirely physical, a view which was adopted by Askenasy, and Dixon and Joly (1895), who realised the significance of the tensile strength of water and on it founded their well-known explanation. Concurrently, the splendid lead given by Pfeffer and de Vries was vigorously followed, and the problems of permeability, osmotic pressure, and, in general, the water relations of the cell, were the subject of hundreds of papers.

Mention also must be made of the progress of knowledge of the gaseous diffusion into and out from the ordinary leaf. F. F. Blackman showed that the evolution of carbon dioxide during respiration and its intake during carbon assimilation was, in general, proportional to the number of stomates on the leaf surfaces. These results were confirmed by Brown and Escombe (1905). Their classic work on the static diffusion of gases was published in 1900, the kernel of which is that the rate of diffusion through the pore of a stomate is governed by the law of diameters.

Turning to metabolism, this third period is remarkable for the clearer focusing of the circumstances attending metabolic activity, and especially of the action and interaction of those factors which influence the rate of particular activities. Before 1905 these factors were considered separately and various optima were given for various functions. The insufficiency of this was soon appreciated by F. F. Blackman, and his application of Liebig's law of the minimum to physiological processes led to his conception of limiting factors. The truth of the doctrine is generally admitted, but the observations of Boysen-Jensen, Harder, Lundegardt, Warburg, and others indicate that a particular factor is only strictly limiting when it is very much weaker than the others.

It has been mentioned that Hoppe-Seyler established a chemical relationship between chlorophyll and hæmoglobin. His work was carried much further by Marchlewski, Nencki, Schunck, and Zaleski. Their work paved the way for Willstätter, who with his fellow-workers, by improved methods of experiment, obtained a number of products—the phytochlorins and the phytorhodins. The fact was established that magnesium is an essential constituent of chlorophyll and that the pigment is an ester of the alcohol phytol. These facts led to the chemical characterisation of two chlorophylls, and, later, of carotin and xanthophyll. A few years after Willstätter and his collaborators elucidated the composition of many anthocyanins.

Of the sequence of events in the elaboration of food stuffs, but little real progress was made. The work of Brown and Morris (1893) on the chemistry and physiology of foliage leaves, in which they recognised sucrose as the sugar first formed in carbon assimilation, is outstanding and was the first of many investigations amongst which the work of Parkin, Davis, Daish and Sawyer, Gast, Kylin and Weevers may be mentioned.

The work of the Darwins, Sachs and Pfeffer on irritability was continued throughout this period, and, indeed, to the present day.

The natural sequence of this tropistic work was an inquiry into the mechanisms of the sense organs. The statolith theory of graviperception, due to Haberlandt and Němec, was, in general, accepted. In addition to those mentioned, Noll, Czapek, Jost, Vöchting, Oltmanns, de Vries, and Rothert contributed much to the elucidation of the problems. There remained the question of the transmission of the stimulus from the perceptive organ to the motive region. Boysen-Jensen (1910) showed that a stimulus could pass through a water-gap but not through a thin plate of mica. Thus arose the idea that definite bodies, hormones, were generated in the perceptive region by the action of the external agents and travelled to the motive organs to activate the visible reaction. These observations were continued, and amongst those who contributed were Nielson, Paàl, Purdie, Rothert, Stark, Dreschel, Snow, and especially Went.

Present-day Botany.

The present period is chiefly remarkable for the great output of work in those branches of botany which have an applied aspect. Thus mycology, plant pathology, genetics and cytology occupy a prominent position. In physiology, but little progress has been made in the elucidation of the serial events of the various metabolic changes. But the closer examination of the governing factors, the conditions of growth and the more detailed analyses of these activities, have secured our knowledge, inadequate though it be, more firmly, and also have disclosed certain relationships of first-rate importance, hitherto unsuspected —photo-periodism, in which Garner and Allard were the pioneers; the carbohydrate-nitrogen ratio, to our knowledge of which Kraus and Kraybill have contributed much; and the principle of predetermination so clearly demonstrated by Balls. The application of the principle of the hydrogen ion concentration has given an instrument of great precision capable of use in the investigation of a wide range of problems. The cell wall constituents have been the subject of intensive investigations, some dictated by the requirements of industry, and important discoveries and elucidations have been made.

A survey of this period shows two well-defined tendencies: specialisation and the obliteration of the artificial margins between botany and cognate studies.

The study of physiology in particular and of many aspects of ecology require the application of the technique and conceptions of physics and especially of chemistry: this will increase in the future; if the approach to such problems be made from the biological point of view, progress will be more assured.

The stress of the War soon forced lessons home, and amongst other things learnt was the dependence of man on the plant. The experience of the War was, curiously enough, not forgotten when peace came, with the result that the training of young botanists for economic work and for the investigation of definite problems became with time a settled policy. But other nations also have learnt the lesson—low living ever has been an incentive to high thinking—with the result of gross over-production—some prefer to call it under-consumption—of essential commodities such as wheat, sugar, and rubber. This is mostly due to the unconsidered use of the great advances of applied botanical knowledge and of agricultural engineering without regard to economic consequences. The present tendency in States and industries to curtail expenditure on research and expert knowledge is a wrong policy: "They that be whole need not a physician, but they that are sick".

The successful conduct of these and many like activities is impossible without expert advice. In Great Britain this is provided by many research stations, and their development is all to the good. But there are a few dangers. The founders of new research institutions may be unmindful of the fact that results cannot be commanded. This may react on the investigators, who may be tempted to justify themselves by the dissemination of unripe fruit. Again, the promotion of applied research may tend to obscure the value of pure research. Lastly, there is the comparative isolation of the workers from their academic brothers so that both lose a source of stimulation and ideas. These possible dangers will be eliminated if there be some connexion, the closer the better, between the botanical departments of universities and the research institutions, accompanied by an occasional interchange of the workers in both.

The British Commonwealth of Nations is, in the main, an agricultural Empire: the great need for trained botanists for its administrative and technical service is patent; the problem is their supply and their training. The increased demand is slowly having its effect in the universities, and more students are taking botany for their finals, but their numbers are too few. In the university the training of young botanists for the first three years must be in pure science; this is absolutely essential, and should be followed by a period of appropriate specialised training.

This raises the problem of the manning of our botanical departments: universities cannot compete with industry in matters of salary, and this in the past has resulted in good men being lost to academic work, especially in plant physiology. If good material for the service of the State and of industry is to be provided and pure research maintained, an adequate flow of recruits of the highest quality into academic life is essential.

Forms of the Solar Corona and their Origin.

By Dr. WILLIAM J. S. LOCKYER, Norman Lockyer Observatory, Sidmouth.

IT has long been known that the solar corona undergoes cyclical changes of form synchronising approximately with the eleven-year period of solar activity as determined by the variation of the spotted area on the solar surface from year to year.

These forms are so pronounced and distinctive that they can be classified into three main types, known as 'Polar', 'Intermediate', and 'Equatorial'. The characteristics of the types are as follows :

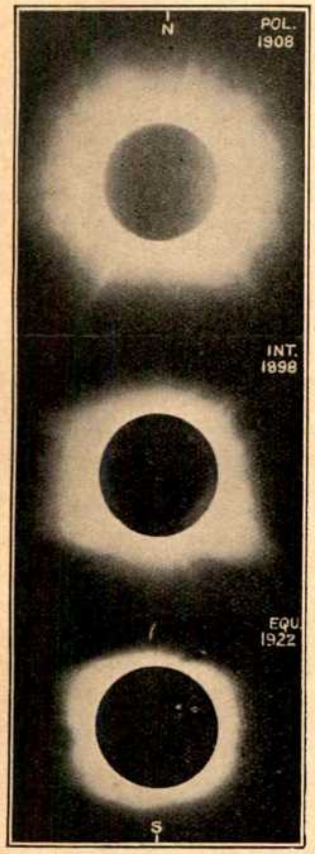

FIG. 1.—Types of solar corona.

(1) The 'polar' type includes those irregular forms in which the streamers are situated all round the solar disc; the polar 'rifts' or 'plumes' in this type are conspicuous by their absence. This type is usually termed the 'maximum' or 'maximum sunspot' type.

(2) The 'equatorial' type is exhibited when the streamers are restricted to comparatively low solar latitudes, and the poles display the 'polar rifts' to the best advantage and have a large spread in latitude. This type is sometimes termed the 'minimum' or 'minimum sunspot' type, and also the 'wind-vane' or 'fish-tail' form.

(3) The 'intermediate' type displays the streamers in mid-solar latitudes. The 'polar rifts' are present, but not so extensive in latitude as in the 'equatorial' type. The streamers also approach nearer the polar regions than in the 'equatorial' type, while the equatorial extensions are not in such great evidence. This type is sometimes referred to as the 'square corona', and 'intermediate' between sunspot maximum and minimum type.

Illustrations of these types are shown in Fig. 1, and the coronas are so oriented that their north poles are situated at the top of each, and can therefore be compared directly with one another as regards the positions of the polar 'rifts' and 'steamers'. The corona at the top represents the 'polar' type (1908), and it will be seen that long streamers are situated in nearly all solar latitudes and the polar rifts are absent. The corona is very extensive all around the dark moon, owing to the sun being at its maximum state of activity.

The next lower figure represents the 'intermediate' stage (1898), the polar rifts becoming apparent. The corona takes a square form, the main streamers radiating more in mid latitudes. In the last form, that of the 'equatorial' type (1922), the polar rifts are well pronounced and the whole corona is not so extensive all round the disc. It is difficult, however, to show the extent of the equatorial streamers, as they are much fainter than usual and to some degree become lost in the reproductions.

Owing to these changes of form varying with the sunspot curve—that is, the 'polar' forms synchronising approximately with the maxima of spotted area, the 'equatorial' with the minima of spotted area, and the 'intermediate' with the intervals between these maxima and minima—all investigators who have studied this subject have concluded that these changes of form were due to the sunspots themselves.

When we come to examine the positions of spots on the solar surface, it is found first of all that they are never near the poles at all. The highest latitude they ever attain is somewhere about 45° north or south, and this occurs only at about the time when the spots are very small and the sun at a low state of activity. When, however, the sun is most active and the spotted area at a maximum, their mean latitude is only about 15° north and south.

It will thus be seen that the presence of the spots themselves cannot possibly be the origin of the coronal streams at the poles of the sun, because at the epochs of the occurrence of the latter phenomena the spotted activity is at a maximum in latitude 15°, a very long way away from the poles. If, therefore, the spots do not cause the polar streamers, then there is no reason why they should account also for the streamers which occur in the spot zones. There must, therefore, be some other form of solar activity which gives rise to these brilliant streamers which can radiate from any latitude.

When the frequency of occurrence of solar prominences is studied closely it is found that, from year to year, they wax and wane, synchronising approximately with the variation of the sunspot areas. Thus it may be said that the curves representing prominence frequency and spotted area are very closely allied or similar, and if the changes in the coronal forms follow closely those of spotted area, they may equally be stated to follow also those of the prominence frequency.

Prof. Ludendorff, in 1929, made a very detailed study of this subject of the cause of the changes of coronal form, and concluded that this change varies with the sunspot period. He did not add that it corresponds with the frequency of prominences as well, but if he had, his deduction would have been correct. The great advantage of accepting prominence action rather than spot action as the cause of the coronal streams is that prominences *can occur in any latitude*, even at the solar poles.

To illustrate the distribution in latitude of the prominences on the solar disc year by year, reference may be made to Fig. 2, where the latitudes are given for each year from 1870 to 1929 for both hemispheres of the sun. In this figure the other solar changes already mentioned are also inserted, so that they can all be compared with one another on the same time scale. Thus, the first two curves show the strong similarity between the variations of the spotted areas and the prominence frequencies, and the approximate similarity of epochs of their maxima and minima. The third curve displays the change of latitude of the mean spotted area for each year for both hemispheres, demonstrating the movements towards the equator of the spot zones from a sunspot minimum to the following minimum. The vertical continuous lines show the epochs of sunspot maximum, and the vertical broken lines those of sunspot minimum.

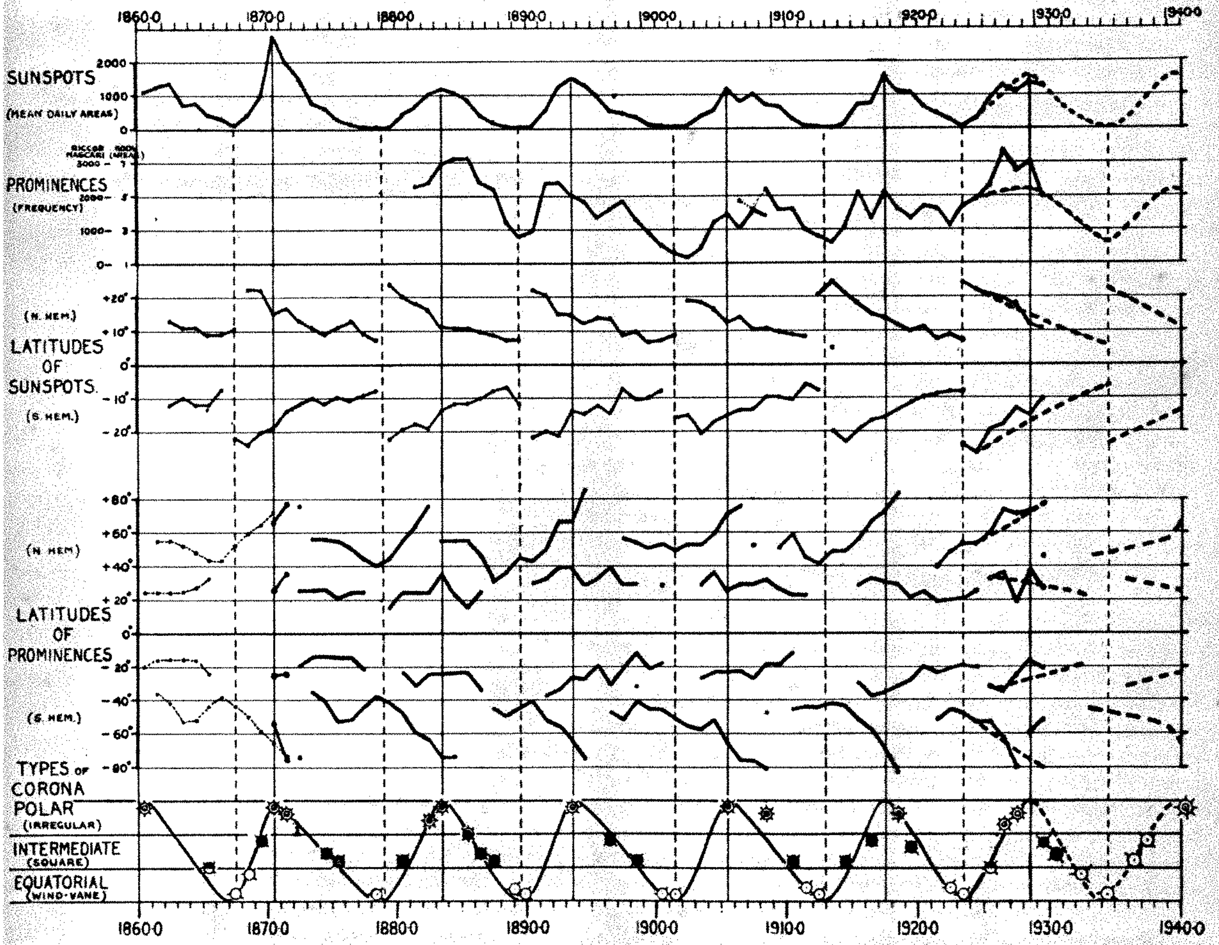

FIG. 2.—Periodicity of solar phenomena. Reproduced by courtesy of the Royal Astronomical Society from *Mon. Not. R.A.S.*, vol. 91.

Coming now to the fourth series of curves, namely, those showing the latitudes of the prominence zones from year to year, it will be seen that in both hemispheres there are nearly always two zones of prominences in action simultaneously.

That which may be termed the 'low-latitude zone' commences two to three years after sunspot minimum, tends to move (like the spot zone) to lower latitudes, and disappears generally about two years before the next sunspot minimum. The other zone, which may be called the 'high-latitude zone', commences about three years after sunspot maximum, and moves towards the poles in each hemisphere, terminating generally very abruptly close to the poles about a year after sunspot maximum. At about the sunspot minimum there is usually a period of about two or three years when only one prominence zone is in operation, and that is the 'high-latitude zone', which is then situated in about latitude 45° in each hemisphere.

When the sun is most active, as exhibited by either spots or prominences, the latitudes of the prominences exceed 60° in both hemispheres *in every case*, except in the year 1928, when it was at 60° in the southern hemisphere only. Attention should specially be directed to the fact that the *highest* prominence latitudes do not necessarily occur *at* the sunspot maxima, but more generally about a year later, and in one instance, namely, in 1908, the highest latitude was attained in the southern hemisphere *three years* after the sunspot maximum.

Below these prominence latitude curves are shown the forms of the corona as observed at each eclipse. These are arranged in three horizontal strips, the uppermost one containing all the 'polar' forms, the middle the 'intermediate', and the lowest the 'equatorial' forms. Each eclipse is placed in the year of its occurrence, according to the time scale given at the top and bottom of the figure. The continuous curve represents simply a smooth curve passing through the maxima and minima points, thus representing the sunspot curve.

An important comparison can now be made between these coronal types and the prominence latitudes. The first point to be noticed is that when the prominences exceed 60° in latitude in either or both hemispheres, the corona is of the 'polar' type in every case. Here, therefore, we have a distant connexion between prominence activity and coronal streamers in the same high latitudes, where spots are never found.

There is also a very close association between the prominences and the other two coronal types. Thus the 'equatorial' forms are recorded when the zone or zones of prominences are in their lowest latitudes; in general, this form is exhibited when there is only one prominence zone in operation. In nearly every case the 'intermediate' types are associated with two zones of prominences in each hemisphere.

Another interesting point arising out of these prominence latitude curves is that, according to the distribution of the prominences, there seems little doubt that the 'intermediate' type of corona takes on two forms, one as it occurs when the sun is increasing its activity and another when the sun's activity is on the wane. This difference is shown in the following table. In this the mean latitudes of both the high- and low-latitude prominence zones for each hemisphere, as shown in Fig. 2, are tabulated for each form of corona, and the 'intermediate' type is divided into two forms, 'intermediate up' and 'intermediate down'.

Corona Type.	Prominence Zones.						No. of Eclipses.
	High Latitude.			Low Latitude.			
	S.H.	N.H.	Mean.	S.H.	N.H.	Mean.	
	°	°	°	°	°	°	
Equatorial . .	45·5	44·4	44·9	20·0	22·5	21·2	9
Intermediate up .	51·5	58·5	55·0	30·6	30·6	30·6	4
Polar . . .	71·6	70·5	71·0	26·5	29·5	28·0	10
Intermediate down .	46·8	51·7	49·2	20·7	25·0	22·8	9

While there are only four eclipses of the 'up' type, but nine of the 'down', the latitudes of both the high- and low-latitude zones are greater in the former than in the latter.

Thus for the high-latitude zone the mean latitude for the 'up' is nearly six degrees higher than that for the 'down', and for the low-latitude zone the 'up' exceeds the 'down' by nearly eight degrees. This difference, which is in the same direction for both zones, seems to be sufficiently large to suggest that there may be a small change of type at the times of the rise and fall of solar activity.

It seems most probable that the form of the corona seen at any eclipse is not the immediate result of the presence of prominences at that particular moment. It seems more likely that the form is the result of long-continued action of the prominence zones, for weeks or maybe months, previous to the eclipse. If, for example, the prominences recorded on the sun for two or three months previous to an eclipse occurring were examined, it is most probable that the form of the corona could be well anticipated.

Using data selected from the years 1912, 1916, 1918, 1919, and 1923, since eclipses occurred in these years in which the coronal forms were recorded as of the equatorial, intermediate up, polar, intermediate down, and equatorial types respectively, an attempt was made to see if they reflected the chief types of the corona.

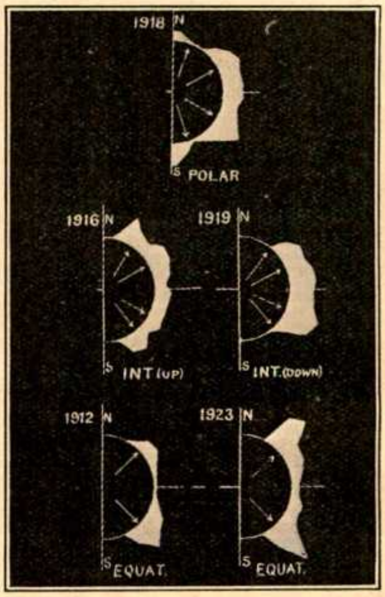

FIG. 3.—Coronal types in relation to latitudes of prominences. Reproduced by courtesy of the Royal Astronomical Society from *Mon. Not. R.A.S.*, vol. 91.

These yearly mean prominence areas were then plotted for each ten degrees of latitude, as shown in Fig. 3, for each of the five years, the same scale being used throughout; this scale has, however, no special relation to the areas of the dark half suns, which are all of the same size. The sequence to be followed is from bottom left-hand side up to top right-hand side down.

It will be seen that the main features of the coronal types are all reflected in the prominence distribution in latitude, the high-latitude zones moving towards the poles simultaneously with the greater area of prominence activity, and reaching the poles at the epoch of the 'polar' type of corona. The 'equatorial' type is conspicuous by having only one prominence zone in each hemisphere.

There is here a decided difference between the prominence distribution in the 'intermediate up' and the 'intermediate down', the latter, in this instance, conforming more to the equatorial type, disregarding the greater area of prominence activity there displayed.

The white arrows in each of the five half suns are the plotted positions of the latitudes of the high and low prominence zones extracted from the table previously given, and show the *mean* positions of these zones from all the eclipses of each type. It will be seen that, for this single series of years, the arrows conform very well to the actual positions of the prominence zones.

Another attempt was made, but this time only using data for the second half of the same years as indicated in Fig. 3. In this case the prominence areas displayed, quite astonishingly, practically the same distribution in latitude, and thus exhibited the same forms. These computations suggested very strongly that an actual corona is really the sum total of a prolonged prominence action previous to its appearance at an eclipse.

It will be noticed in Fig. 2 that from the year 1925 all the curves have been continued up to the year 1940 by broken lines. These were inserted in 1925 to attempt to forecast the changes in the different solar phenomena from year to year. Comparing those curves with those now available up to the year 1929, it will be seen that they conform fairly well with the actual facts. It was at that time considered probable that the high-latitude prominence zone would be still in evidence in both hemispheres in the year 1929 in about latitude 80°, and would therefore give rise to a 'polar' type of corona for that year. The latitude of this zone was, however, not so accommodating, but only actually reached 52° in the southern hemisphere and 44° in the northern hemisphere, so that an 'intermediate' type of corona should have been expected and was actually recorded.

In the case of the next few total solar eclipses following that of 1930, namely, those for the years 1932, 1934, 1936, 1937, and 1940, the forecast curves suggest that the 1932 corona may be of the 'equatorial' or on the boundary between an 'intermediate' and 'equatorial' type; that the 1934 corona will be of the pure 'equatorial' type; that the coronas of 1936 and 1937 should display an 'intermediate' type; and, finally, that the 1940 corona should be of the 'polar' type, owing to the position of the high-latitude prominence zone, which should then be in about latitude 70° in both hemispheres.

It is satisfactory to record that, since my first communication to the Royal Astronomical Society in 1903, showing that the prominences are responsible for the varying shape of the solar corona, this view has been endorsed by J. Evershed in 1908 and by Prof. Osten Bergstrand in 1930.

Gassendi and the Transit of Mercury.

THREE hundred years ago, in November and December 1631, the first accurately predicted transits of both Mercury and Venus took place, but only the transit of Mercury was observed. Kepler many years before had stated that Mercury would cross the sun's disc on May 20, 1607, and carefully but vainly watched for it. With the completion of the Rudolphine Tables in 1627, he again took up the problem of determining the times of transit, and in a small tract published in 1629, entitled "Admonitio ad Astronomos rerumque celestium studiosos, de miris rarisque anni 1631 phaenomenis . . .", announced that Mercury would pass over the sun's disc on Nov. 7, 1631, and Venus on Dec. 6, 1631. He announced at the same time that there would not be another transit of Venus before 1761, but in this he was in error.

Only one person was fortunate enough to observe the transit of Mercury predicted by Kepler, and this was Gassendi, who then, at the age of thirty-nine years, was already recognised as one of the foremost French philosophers. Some years afterwards, Gassendi became professor of mathematics at the Collège Royale in Paris and by his lectures and writings did much to stimulate an interest in science, but in 1631 he was provost of the Cathedral at Digne, near which he was born. He had been a precocious youth, lecturing at the age of sixteen and at the age of twenty-one becoming a professor of theology and philosophy at Aix. Among his contemporaries he counted Mydorge, Mersenne, and Descartes, while among his correspondents was Galileo. He was in Paris at the time of the transit and he gave an interesting account of his observations to Schickhard, professor of mathematics at Tubingen, a man as learned as himself.

Speaking of his observations, Gassendi said: "The crafty god had sought to deceive astronomers by passing over the sun a little earlier than was expected, and had drawn a veil of dark clouds over the earth in order to make his escape more effectual. But Apollo, acquainted with his knavish tricks from his infancy, would not allow him to pass altogether unnoticed. To be brief, I have been more fortunate than those hunters after Mercury who have sought the cunning god in the sun. I found him out, and saw him, where no one else had hitherto seen him."

Gassendi had arranged to see the transit by admitting solar light into a dark room through a small hole and receiving the image of the sun upon a white screen marked with a circle divided into sixty parts. He placed an assistant in a room above, to observe the altitude of the sun with a 2 ft. quadrant, and to signal. Nov. 5 and Nov. 6 were both rainy and overcast and the morning of Nov. 7 broke with the weather still changeable. But fortune favoured him in the end and he was able to observe the planet some time before it passed off the disc about 10.30 A.M. He calculated that the transit had taken five hours and had occurred about four and three-quarter hours before the predicted time.

The second predicted transit of Mercury occurred on Nov. 3, 1651, and was observed at Surat in India by the young English astronomer, Jeremy Shakerley, who had gone to that country for the purpose; while the third transit recorded by astronomers was on May 3, 1661. This was observed by Hevelius at Dantzig and by Huygens, Street, and Mercator in London.

Immediately after his observation of the transit of Mercury, Gassendi prepared to observe, if possible, the passing of Venus across the sun; for although this had been predicted to take place about sunset on Dec. 6, he considered that a possible error in the calculations might afford him the opportunity of seeing it. Dec. 4 and Dec. 5 were both stormy; Dec. 6 gave him glimpses of the sun, and the sun was visible all the forenoon of Dec. 7. He saw nothing, however, and it was afterwards shown that the transit took place during the night between Dec. 6 and Dec. 7. Eight years later, the first recorded transit of Venus was observed, on Nov. 24, 1639, at Hoole, eight miles from Preston, Lancashire, by the young clergyman, Jeremiah Horrocks, and his companion, William Crabtree.

Gassendi died in 1655 at the age of sixty-three years and was buried in the Church of St. Nicolas-des-Champs, Paris; while Horrocks died in 1641 at twenty-three years of age and was buried in the ancient chapel of Toxteth Park, a monument being erected to him in Hoole Church in 1826 and another in Westminster Abbey in 1874.

Obituary.

DR. DAVID STARR JORDAN.

DR. DAVID STARR JORDAN, who died in California on Sept. 20, was for many years a prominent leader in the promotion of biological science and higher education in the United States. He was born at Gainsville, in New York State, on Jan. 19, 1851, and after attending a local school gained a scholarship at the newly founded Cornell University in 1869. There he graduated and began his active career as instructor in botany.

Jordan's first original papers, published in the *American Naturalist*, were on botanical subjects, but in 1873 he had the opportunity of attending the summer school of Louis Agassiz at Penikese, and henceforth his chief interest was in fishes. During the next few years he worked most industriously at systematic ichthyology, publishing several noteworthy papers, and in 1879 he was appointed professor of zoology in Indiana University. He was not only keen in research but also endowed with administrative ability, and in 1885 he became president of the University. There he remained until 1891, when he was elected first president of the Leland Stanford University in California, and rendered distinguished service to this new foundation until his retirement in 1916. As an acknowledgment of his work, he was eventually made chancellor emeritus of Leland Stanford University.

While occupied with academic duties, Jordan found time to take part in many other scientific and educational activities, and even in political discussions. From 1879 until 1890 he was closely associated with the United States Fish Commission, and in 1880 he was in charge of fishery investigations on the Pacific coast. In 1896–97 he was the American representative on the commission for studying the fur seals in the Bering Sea, and in 1898 he published (with the aid of George A. Clark) an official " Report of Fur Seal Investigations ". He was always active in organisations for the abolition of war. His varied reminiscences were published in 1922 in two volumes entitled "The Days of a Man ".

Jordan's researches on fishes were chiefly concerned with the naming of genera and species and their systematic arrangement. He made a special effort to examine personally the older collections, to determine precisely the meaning of many of the earlier names which had been given without adequate definition. Helped by his pupils, who were usually joint-authors of his papers, he then proceeded to describe and name some hundreds of new forms, not only from North America, but also from Japan, the Philippines, and Hawaii. In 1883, with C. H. Gilbert, he published a " Synopsis of the Fishes of North America ", and in 1896–1900, with B. W. Evermann, he prepared and published in four volumes a still more elaborate work on " The Fishes of North and Middle America ". In 1905 he issued a more general " Guide to the Study of Fishes ", in two volumes. Between 1917 and 1920 he aided systematic ichthyology by preparing a list of all the genera of fishes named between 1758 and 1920, with an indication of the type species of each—a work published in four parts by Leland Stanford University. In 1923 he supplemented this by " A Classification of Fishes " in the same University's publications. In his later years, Jordan was stimulated, by the discovery of numerous fishes in the Tertiary diatomaceous earth of California, to describe and name fossil fishes both from North America and from Brazil, but the results were not very satisfactory.

Throughout his career Jordan's influence on the systematic study of fishes in North America was indeed great, and he has left several devoted pupils to continue and extend his work. A. S. W.

WE regret to announce the following deaths:

Prof. James S. C. Douglas, Joseph Hunter professor of pathology in the University of Sheffield, on Oct. 30, aged fifty-two years.

The Rev. Dr. T. C. Fitzpatrick, president of Queens' College, Cambridge, and formerly a demonstrator in the Cavendish Laboratory, on Oct. 28, aged seventy years.

Dr. James W. Gidley, assistant curator of fossil mammals in the United States National Museum, on Sept. 26, aged sixty-five years.

Mr. Alfred J. Henry, senior meteorologist in the United States Weather Bureau, on Oct. 5, aged seventy-three years.

Prof. Guido Holzknecht, professor of medical radiology in the University of Vienna, and honorary member of the British Institute of Radiology, who was one of the pioneer workers in the application of X-rays to medicine, aged fifty-eight years.

News and Views.

IT is announced in the *Times* of Oct. 30 that the Nobel Prize for Medicine for 1931 has been awarded to Prof. Otto Warburg, of the Kaiser Wilhelm Institute for Biology, Berlin-Dahlem. Prof. Warburg is known for his work on the metabolism of tumour tissues, which is a development of his researches, commenced about twenty-five years ago, on the respiratory processes of cells and tissues. The earlier work was concerned mainly with the utilisation of oxygen by sea-urchin eggs and red blood cells; his later investigations have shown that tumour cells have a characteristic type of metabolism. In the presence of oxygen, lactic acid is produced, whereas the majority of normal tissues only produce the acid in the absence of oxygen; in its presence they oxidise it or resynthesise it to some more complex substance, such as glycogen. In other words, tumour cells appear to obtain the energy they require, or at any rate part of it, from the simple breakdown of sugar to lactic acid, whereas in normal tissues the further oxidation of the acid to carbon dioxide and water is required to supply the energy for their metabolic processes. The distinction between the two types of respiration, however, is not absolute: thus, tumour tissues also consume oxygen, whilst normal cells can be made to develop the abnormal type of metabolism by interfering with their respiration. Warburg's view of the origin of cancer is that it depends upon this abnormal development of aerobic glycolysis: in most cases this change in the type of metabolism leads to death of the cell; if the cell lives, however, a tumour results.

FURTHER information is now to hand regarding the discovery of element No. 87, to which reference was made in NATURE of Oct. 24, p. 696. Papish and Wainer, in the October number of the *Journal of the American Chemical Society*, describe some preliminary experiments in which samarskite was treated for the removal of elements before the alkali metal group, and the alkali metal fraction, in the form of the least soluble alum fraction, was examined in the X-ray spectograph. Five lines corresponding with the element 87 were obtained by excitation in a Siegbahn vacuum apparatus of high dispersion, the absence of tungsten, gold, and tin, which would have caused interference, being established by special experiments. Previous experiments by an optico-magnetic method made by Allison and Murphy in 1930 had led to the conclusion that element 87, which belongs to the alkali-metal group, was present in minerals rich in the rarer alkalis. Preparations from lepidolite and pollucite, which gave indications of the presence of comparatively large amounts of element 87 by the optico-magnetic method, were found, however, not to contain it by chemical and optical tests. The element 87 is regarded as non-radioactive or very feebly so, but it may be an inactive residue from the disintegration of radioactive elements of existing series or of a series long extinct. The samarskite used was rich in uranium and also contained rubidium and cæsium.

SIR CYRIL KIRKPATRICK's presidential address to the Institution of Civil Engineers, delivered at the opening meeting of the session on Nov. 3, was on "The Tidal Thames"—a subject full of historical and engineering interest. By a charter of Richard I. in 1197, the citizens of London became conservators of the river Thames from London Bridge to Colnie Ditch, now the river Colne, near Staines, where the boundary stone, dated 1280, is still in existence. By an Act of 1489 the river came under the direction of the Mayor and Corporation of London. In 1771 a Committee of the Corporation took over the duties. In 1857 a new Board, the Conservators of the River Thames, was created, and this Board was succeeded, on March 31, 1909, by the Port of London Authority; the upper section of the river above the landward limit (about 265 yards below Teddington Lock) remained under the Conservators, and the lower section under the Authority. The dredging of the river was taken over by the Port Authority in 1909, and the total quantity of material removed to the end of the year 1930 was 41,768,747 cubic yards, as measured in the hoppers. Reference was also made to dredging for ballast, which in the sixteenth century was a privilege of the Lord High Admiral of England and later of Trinity House. In 1861 there was shipped in the Port of London as ballast 202,915 tons of chalk and 565,700 tons of shingle. Owing to the introduction of water ballast during the nineteenth century, the dredging of ballast from the Thames for the use of vessels became no longer necessary.

DEALING next with the constructional works carried out in connexion with the Thames, Sir Cyril Kirkpatrick stated that in 1909 the area of dock water was about 641½ acres and the length of quays about 27½ miles. Since that date, the most noteworthy additions have been King George V. Dock and a new entrance lock and passenger landing-stage at Tilbury. The area of dock water is now about 723 acres, and the length of quays about 33 miles. The total capital expenditure incurred by the Authority on new works was over 14 million pounds. The total net register tonnage of vessels entering and leaving the port had increased from 38½ millions in 1909 to 57½ millions for the year 1930. Referring to the principal industries associated with banks of the Thames, Sir Cyril stated that shipbuilding practically disappeared with the substitution of iron for wood in shipbuilding and the introduction of steam propulsion. About 4½ million tons of coal are carbonised annually at the riverside gasworks for the production of gas, which is distributed by upwards of 7000 miles of mains. The coal is brought up the river by the companies' own steamers to their wharves, and the by-products amount to more than one million tons a year. Another very important industry is the generation of electricity for lighting and power. It is estimated that more than 650 million tons of water are borrowed from the river annually by electric power-stations for circulating water. It is expected that by 1935 the number of units will have increased to 3500 million, the consumption of coal to 2,200,000 tons, and the water required to more than 1000 million tons. A very important commercial undertaking is that of the Ford Motor Company at Dagenham, equipped with the first blast-furnace built on the Thames. Extensive depots for crude petroleum, motor-spirit, and lamp-oil have been established at Thames Haven in Sea Reach; more than three million tons were imported during 1930.

LIEUT.-COL. E. KITSON CLARK in his presidential address to the Institution of Mechanical Engineers, delivered on Oct. 23, forsook the usual path of a president who feels it his duty to deal with the particular branch of engineering he has been engaged on and thus give the members the benefit of his experience, and devoted his remarks entirely to hammers, hammering, and humanity. His title, indeed, was "Humanity under the Hammer". Claiming that mechanical history began with the hammer, he traced the evolution of hammers from palæolithic and neolithic man down to the present time, exhibiting and illustrating many types of both hand and power hammers, and we should not be surprised if his address comes to be regarded as a classic on the subject. Engineering knowledge, a love of antiquarian lore, a philosophic outlook, and a sense of humour were all brought to bear on the matter in hand. Whether it was the hammer of the flint knapper, the hammer of the coppersmith, the stone-mason, the gold-beater, each and every kind brought out some interesting and often unexpected point, and history, mythology, poetry, and religion were all called upon to contribute to the discussion. The plain story of the hammer, indeed, became a philosophy; and in the romance of the story there were to be found some essences of principles which are by no means settled, and even some reflections of the greatest issues of existence. Lieut.-Col. Clark said: "Let us reverence the unknown, determined, wherever we may find ourselves, to be ready to strike a blow *mente et malleo*, outside the routine of our allotted task, and try to carry even more than our part of that divine burden placed upon every nation, every family, on every kind and true heart, on every engineer, to leave the world a better place than we found it".

To the great suspension bridges of the United States has recently been added another of much greater span than has hitherto been attempted. The Manhattan Bridge has a span of 1470 ft., the span of the Brooklyn Bridge is 1595 ft., of the Williamsburg Bridge 1600 ft., of the Bear Mountain Bridge 1632 ft., and of the Delaware River Bridge 1750 ft. The George Washington Bridge over the Hudson River, between Upper Manhattan and Fort Lee, opened on Oct. 24, however, has a span of no less than 3500 ft. The main features of the bridge include the two supporting towers, 635 ft. high, in the construction of which about 40,000 tons of steel have been used, and the two pairs of supporting cables, 106 ft. apart. Each of these four cables is 36 in. in diameter and contains 26,474 parallel steel wires, each 0·196 in. in diameter. The wires are divided into sixty-one groups of 434 wires each, special spinning and compacting methods being employed. More than 28,370 tons of cable have been used. The roadway is 256 ft. above the river and has a designed capacity of 30,000,000 vehicles annually, while the addition of a second floor to the bridge will double this capacity. As the outcome of experience with this and other bridges, it is now proposed to construct a suspension bridge at Golden Gate, California, of 4200 ft. span, and another across New York Bay of 4500-5000 ft. span.

THE high cost of patent litigation was among the topics discussed in Section F (Economic Science and Statistics) of the British Association on Sept. 28. Two well-known authorities, Mr. W. H. Ballantyne and Mr. H. A. Gill, reiterated the complaint that has so often been voiced in NATURE—that the expense of patent actions precludes all but the wealthiest corporations from defending their patent rights, and largely defeats the aims of the patent system. The Departmental Committee under Sir Charles Sargant having failed to suggest any effective way of dealing with the difficulty, Mr. Ballantyne proposes a method analogous to that prescribed by the London Building Acts of 1894 and 1930 for the settlement of party-wall disputes. In the case of patents, the parties' patent agents having failed to reach agreement, would agree upon an arbitrator selected from the 'patent bar' or from among experienced expert witnesses, and would submit their cases in writing, with oral amplification if necessary. The parties would be bound by the arbitrator's decision. Mr. Gill referred to the British Science Guild's proposal to utilise the Comptroller of Patents for the settlement of small disputes, a proposal favoured by a minority of the Sargant Committee. He suggested that, failing adoption of that plan, an official referee of the High Court might be appointed for dealing with infringement and validity by a simplified procedure. The matter certainly cannot remain where the Sargant Committee left it.

MR. MAURICE DOBB, in a paper on "Current Economic Theory in Relation to the Five-Year Plan", read before Section F (Economic Science and Statistics) of the British Association on Sept. 29, said that Russia to-day presents to the economist a unique and important type of economic system in three ways. First, it presents a planned economy in which the conscious control of key factors which characterises the operations of a business trust in an individualist system is extended to the economic life of half a continent. Secondly, it presents an example of a socialist economy in the more fundamental social and institutional sense that the former propertied class has been expropriated and the receipt of personal income on property rights has ceased to be the controlling motive over the major part of the economic system. Thirdly, the aim of the Five-Year Plan is to effect an epoch-making industrial revolution of the whole country so that a backward agrarian economy may be transformed to one based on the most up-to-date American technique. Under the Five-Year Plan about thirty per cent of the national income is to be devoted to capital investment (or a proportion double that in pre-War Great Britain). Giant schemes are being undertaken, such as the half-million kilowatt Dnieper Dam scheme, the Stalingrad tractor plant (the largest of its kind in the world), the Nijni-Novgorod automobile plant with a capacity of 150,000 machines a year, and the State Farm, 70 miles by 30 miles in extent.

MR. J. F. SCHOFIELD, of Durban, writes to suggest that Great Zimbabwe may have been occupied at a much later date than is generally thought, and, in fact, may have been abandoned so recently as 1825, at the time of the Swazi invasion. The evidence upon which this conclusion is based is threefold. Wooden lintels would appear to have been used generally for the door openings in the girdle-wall of the 'Temple' and the west wall of the 'Acropolis'; but no one who has a practical acquaintance with the use of timber, especially in the form of logs retaining the outer sap-wood, in sub-tropical countries, would estimate its life at the five hundred years required by Miss Caton-Thompson's dating, still less the twelve centuries demanded by Frobenius. The date of the girdle wall and the wall of the Acropolis must be compatible with timber construction. In the second place, where the upper courses of the walls have been damaged by the branches of trees, the existing trees are the cause; but none of these is a hundred years old. Consequently the buildings must have been kept clear of vegetation up to a hundred years ago. In the third place, in view of the rapid change of ground level owing to the torrential rains of Rhodesia, it is improbable that the drain-hole through the wall noted by Bent would have been still overground in 1892 if it had been constructed more than a short time before Zimbabwe was abandoned. Mr. Schofield therefore concludes that, taking Miss Caton-Thompson's date of A.D. 800 as the earliest date of occupation, the latest and finest work was not completed until about A.D. 1775.

DECREASES in the number of samples examined during the year ended March 31, 1931, at the Government Laboratory and its branches reflect the present depressed state of industry. During the year the total number of samples was 517,462, compared with 545,422 in the preceding year. The report of the Government Chemist, Sir Robert Robertson, surveys the activities of the laboratories at Clement's Inn Passage, London, at the Custom House, London, at certain of the more important seaports, at the Geological Survey Museum, and at the War Office Supply Reserve Depot, Deptford. While most of the work is of a routine character, concerned with the protection of public health or State revenues, much investigation has to be continuously undertaken both to keep abreast of advances in manufacture and industry and to improve the processes of analysis. Moreover, the Government Chemist is frequently consulted by Crown Departments on such chemical problems as from time to time arise, and representation of the Laboratory on committees frequently necessitates experimental investigations. Among the subjects on which advice was sought was the protection, particularly from insects and the effects of moisture, of water-colour drawings in West Africa; the use, in frames, of hermetically sealed, glass-fronted metal cases was recommended. A sample of soot from burners using oil as fuel was found to contain free sulphuric acid; this explained its irritant action on a worker's mouth and throat. The causes of the deterioration of cinematograph films of national importance, and means for restoration and preservation, have been studied. The damage was traced to inefficient washing or to the use of weak or exhausted 'hypo'; improved methods of washing, together with final treatment with fresh 'hypo' and subsequent washing, were advocated.

AMONG the foodstuffs examined at the Government Laboratory was brown sugar which contained a considerable proportion of formic acid, either produced during the process of refining or added as a preservative. Three samples of tinned vegetables contained copper colouring matter. Although the abolition of the duty on tea has removed the necessity for the examination of tea denaturants or tea for export, all consignments are examined on importation to ensure that no tea other than that which is pure and fit for human food shall pass into the country. Sea-water samples are examined in connexion with a scheme of oceanic research carried out by the Fisheries Department of the Ministry of Agriculture and Fisheries and by the Fishery Board for Scotland, acting in concert with the International Council for the Exploration of the Sea. The objects of the investigations are "to determine the influence upon fish life of the salt concentration or salinity, and to trace the movements of the water, apart from tidal ebb and flow, from one part to another in the sea. The sea-water in the Atlantic is more salt than in the North Sea, and the drift of the water from place to place can be traced by making periodical measurements of the salinity at definite positions and charting the results." Imported cheese was found to vary considerably in water and fat content; less than half of the samples had been prepared from whole milk. Yet no exception could be taken, since there are no regulations relating to the marking of skimmed or partially skimmed milk cheese. Likewise, since there is no standard for cream in Great Britain, no action could be based on the fact that only seven per cent of the samples of cream contained 45-55 per cent of fat, the remainder containing only 19-35 per cent. Other important work has been concerned with the administration of the hydrocarbon oils duty, and with the accuracy of hydrometers.

IT has again proved worth while to provide a class at the Dairy Show at Islington for Muscovy ducks only—this species, after being neglected in England for a generation or so, and ignored or disparaged by most writers on poultry, having again come into prominence. Descended from the *Cairina moschata* of the warm regions of America, this duck is one of the few domestic-animal contributions of aboriginal American culture, the others being the llama, guinea-pig, and turkey; and, although less generally known, it has become more widely distributed than any of these, being kept even by savages in Africa and Polynesia. This is not surprising, as it is far more tolerant of unnatural conditions than the domestic ducks of mallard descent, and will rear its young with as much devotion as any hen. Curiously enough, though more sluggish than any other kind of poultry, it has not lost the power of flight, although its domestication, for all we know, may have been more ancient than that of the mallard. Another curious fact about it is that, although naturally black, it but rarely produces a slate-coloured or 'blue' variety, whereas 'blue' ducks of mallard descent are frequently to be seen; as blue-grey is supposed to be a dilute form of black, this is exactly the opposite of what might have been expected, the mallard having little black in its coloration.

THE Mongolian wild horses at the London Zoological Gardens are now assuming their thick winter coat, which, curiously enough, is bay, not dun, like the short summer pelage. The beasts are thus darker and brighter in colour in winter than in summer, showing the exact reverse of the change undergone by the northern race of the tiger. A more marked change in seasonal colour in the same direction is to be found in the chamois, which is brown in summer and becomes black in winter; but this is more easily understood as, in a winter world of snow, ice, and rock, black is obviously a colour better adapted to protective concealment than brown. The wild-horse foal born in mid-August this year is, however, growing a winter coat of dun, and as this was the case also with the last foal exhibited, it would appear that the dark rich winter coat is only worn by the older animals, which would be better able to look after themselves. The legs of the foal are beginning to blacken from the hoofs up, the wild-horse foal not being black-stockinged like its parents, and hence falling into line with other wild equines in leg-tint, which in these is either light or only barred with black.

NEARLY a hundred papers, contributed by scientific workers of fifteen nations, are listed in the preliminary programme of the Third International Conference on Bituminous Coal, to be held on Nov. 16-21 in Pittsburgh. The papers cover almost every phase of coal preparation and utilisation. The 'coal' man, it is hoped, will be furnished with an accurate picture of the coal industry throughout the world, and the mine-owner should be helped to predict the future demands for his product by major consumers. A section on the economics of the coal industry has been included because of the desperate condition of the industry throughout the world. The organisers felt that it would be impossible to hold any discussion on coal without considering this problem. Pulverised coal will come in for major discussion. Other sections of the conference will be concerned with gasification, hydrogenation and liquefaction, low and high temperature distillation, coal cleaning and preparation, smoke and dust, by-products, origin and classification, domestic heating, metallurgy, and competition of coal with other fuels.

DURING the last five years, the *Chemiker-Zeitung* has published from time to time reports upon developments of various branches of applied chemistry in the form of special supplements. In the issue of Oct. 14 will be found a twenty-five-page condensed summary by Prof. F. Mayer, of Frankfurt, of advances made throughout the world during the year 1930 in the dyestuff industry. An introductory section outlines the more important experimental lines of progress. This is followed by sections dealing with problems of theoretical interest, particularly those relating to colour and chemical constitution, new methods of obtaining intermediate products, and with the various types of artificial and natural dyestuffs and colours. The report presents, in a form useful for reference, a list of the principal publications and patent specifications relating to the subject, which should be helpful to those who are engaged upon dyestuffs research. The supplement also contains a brief report by Dr. Walter Herzog upon saccharin and its derivatives and on other synthetic sweetening compounds.

THE Report for 1930 of the Strangeways Research Laboratory, Cambridge, has been issued by the Trustees. The Laboratory has continued to make satisfactory progress under the direction of Miss H. B. Fell. The Medical Research Council has continued its financial support, but further endowment is required to extend the work. Experimental embryology and histology have been pursued by means of tissue cultures, and an extensive scheme for research into the effects of radiation upon normal and malignant cells has been organised and is in progress in association with various University departments and with the Addenbrooke's Hospital, Cambridge.

REFERENCE was made recently to an apparently new feature in the floor of the North Sea in the form of a deep trench about 100 miles east of Montrose. It was described by Prof. J. W. Gregory in the *Geographical Journal* for June. A note on the subject is published in the October issue, and it now appears that the Devil's Hole, as it was named, is not a new feature and so has no relation to recent earthquake activity. The feature appears in old fishermen's charts, with a depth of 142 fathoms, but was apparently not recorded on the Admiralty charts, since its exact position was not known. This has now been determined to be some ten miles north and twenty miles east of the position given on unofficial charts. The 'discovery' was thus due to a misunderstanding and recent survey has not recorded any changes on the floor of the North Sea.

THE Rockefeller Institute for Medical Research, New York, has issued a brief account of its foundation and organisation, with a description of the buildings and equipment and present scope of the scientific work. The Institute was founded in 1901 by Mr. John D. Rockefeller with a gift of 200,000 dollars to be expended on grants and fellowships for investigations into the nature and causes of disease and methods of prevention and treatment. With the aid of further gifts, a small laboratory building was rented in 1902, in 1906 a large modern laboratory was erected on a site in New York overlooking the East River, and to this a hospital of 60 beds was added in 1908. A department of animal pathology was created in 1914, located near Princeton University, and it was extended this year to include a division of plant pathology. The Institute is administered by a Board of Trustees and a Board of Scientific Directors, which together constitute the Corporation.

The latest arrangements for the polar year 1932–1933 were outlined in a paper communicated to Section A of the British Association by Dr. G. C. Simpson on Sept. 30. Thirty-five States have agreed to participate in the work, and of these the following are to establish new stations in high latitudes, chiefly within their own territory: Austria, Canada, Denmark, Finland, France, Germany, Great Britain, Holland, Iceland, Japan, Norway, Russia, Sweden, and the United States. The preliminary arrangements have been made to house the British party, which will leave England in May 1932, at Fort Rae, on the Great Slave Lake, where a party was stationed during the original polar year fifty years ago. The party will consist of five. The Government grant will cover the expenses of this station, but further funds will be required if a second station is to be established in Canada and the further project of reopening the Ben Nevis Observatory is to be undertaken. The programme of work arranged by the International Meteorological Committee was referred to in Nature for Oct. 31, p. 754.

Dr. Michael C. Grabham writes from Madeira recalling an incident in 1901 when Lord Kelvin gave him an advance copy of the paper "On the Clustering of Gravitational Matter in any Part of the Universe", which Kelvin read on Sept. 17 of that year at the meeting of the British Association at Glasgow. The incident to which Dr. Grabham refers took place on the eve of his departure for Madeira, and on the same day Crookes had given him a very active speck of radium bromide mounted in the spinthariscope which Crookes had recently invented. This inspired Kelvin to remark on the 'whimsical' objection of those who denied a rigid stellar ethereal medium, and on his own reluctance to accept radium as an element. In view of the theories at present being propounded on "a mathematical reconstruction of a Universe where planets are rare, while here and there in insignificant corners and at infrequent intervals a strange accident results in life stumbling into being", Dr. Grabham expresses a hope that Kelvin's "gravitational paper" may be still surviving. The paper in its entirety appears in Nature for Oct. 24, 1901, p. 626, and in the Report of the British Association, 1901. Lord Kelvin states his arguments still more fully in the *Philosophical Magazine* for August 1901, p. 169.

At the special general meeting of the Linnean Society of London held on Oct. 22, His Majesty the Emperor of Japan was elected an honorary member of the Society.

The seventh annual Norman Lockyer Lecture of the British Science Guild will be given by Dr. H. H. Dale, in the Goldsmiths' Hall, Foster Lane, London, E.C.2, on Tuesday, Nov. 24, at 4·30 p.m. The subject of the lecture will be "Biology and Civilisation".

At the annual statutory meeting of the Royal Society of Edinburgh held on Oct. 26, the following Council was elected: *President:* Sir E. A. Sharpey-Schafer; *Vice-Presidents:* Prof. F. G. Baily, Prof. T. J. Jehu, Prof. J. H. Ashworth, Dr. A. Logan Turner, Dr. J. B. Clark, Prof. James Ritchie; *General Secretary:* Prof. R. A. Sampson; *Secretaries to Ordinary Meetings:* Prof. C. G. Darwin and Prof. F. A. E. Crew; *Treasurer:* Dr. James Watt; *Curator of Library and Museum:* Prof. D'Arcy W. Thompson; *Councillors:* Prof. James Drever, Mr. A. H. R. Goldie, Dr. R. A. Houston, the Hon. Lord Sands, Dr. Murray Macgregor, Dr. A. Crichton Mitchell, Prof. P. T. Herring, Sir Thomas H. Holland, Prof. James Kendall, Prof. T. M. MacRobert, Prof. Godfrey H. Thomson, Dr. Malcolm Wilson.

A new part (pt. II.) of Sotheran's "Catalogue of Exact and Applied Science" (No. 828 of Sotheran's "Price Current of Literature") has just appeared. It deals with works on astronomy, dialling and horology, and physics, and contains, as is usual with the catalogues of Messrs. Sotheran, numerous valuable and interesting bibliographic comments upon the books listed.

Messrs. Dulau and Co., Ltd., 32 Old Bond Street, W.1, have just issued two new catalogues of second-hand books of science obtainable from them. No. 191 gives the titles of nearly a thousand works on botany, gardening, herbals, and allied subjects. No. 192 is devoted to books dealing with conchology, entomology, geology, ornithology, and zoology. Some 300 works are listed.

Applications are invited for the following appointments, on or before the dates mentioned:—A graduate assistant at the Plymouth Day Junior Technical School for Boys, in physics and mechanics—The Secretary for Education, Rowe Street, Plymouth (Nov. 11). A chief handicraft instructor at the Bath Technical College, etc.—The Director of Education, Education Office, Sawsclose, Bath (Nov. 14). A professor of medicine at St. Thomas's Hospital Medical School—The Academic Registrar, University of London, S.W.7 (Nov. 26). A full-time lecturer and demonstrator in anatomy at the University College of South Wales and Monmouthshire—The Registrar, University College, Cardiff (Nov. 28). A professor of anatomy in the University of Lucknow—The Registrar, Lucknow University, Lucknow, India (Dec. 7). A Stevenson professor of international history at the London School of Economics—The Academic Registrar, University of London, S.W.7 (Jan. 8). A bacteriologist at the Wellcome Tropical Research Laboratories, Khartoum—The Director, Wellcome Tropical Research Laboratories, Khartoum, Sudan.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Branching of Lightning.

IT has long been known that the ordinary spark discharge between spherical electrodes exhibits numerous side-branches which are forked away from the positive pole. Similar branching, almost always directed downwards, is shown by lightning discharges between a thundercloud and the ground. For this reason it has been concluded that the direction of branching in a lightning flash is a criterion of the polarity of the discharge (Walter and Simpson). Simpson has examined some five hundred photographs of lightning and has concluded that at least 80 per cent of these pass from a positively charged cloud-base.

This conclusion can be tested from observations of the electric field change at the ground caused by the disappearance of the elevated charge. If the field change is negative, the cloud-pole must have been positive, and vice versa. The method is free from any ambiguity, provided care is taken to exclude multiple flashes which involve more than one charged region; such flashes can be distinguished both by the multiple nature of the field change recorded and by direct observations of the appearance of the lightning.

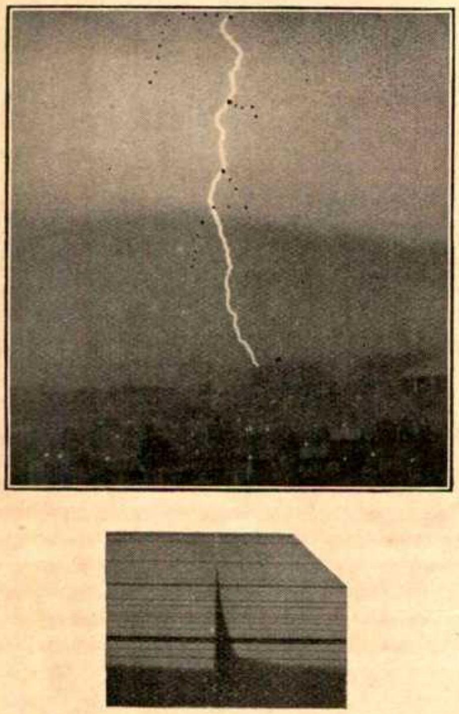

FIG. 1.

Observations of this kind have now been made on more than fifty South African thunderstorms, and indicate that in at least 95 per cent of the 404 flashes examined the cloud-pole was negative. The appearance of these flashes was observed by eye, and the field changes recorded by the capillary electrometer method of C. T. R. Wilson. Photographs of South African flashes to ground show a high preponderance of downward branching (21/24), and suggest, therefore, that in these flashes the branching was the reverse of that observed in laboratories.

Final evidence was obtained by correlating photographic records of the field changes with photographs and sketches of the flashes producing them. Ten such correlations have been made; eight showed that the branching was directed away from the negative pole, and the other two showed no branching and were possibly partly obscured by rain. One such correlation is shown in Fig. 1—this was a single flash to ground; the branches have been emphasised by dots placed above them.

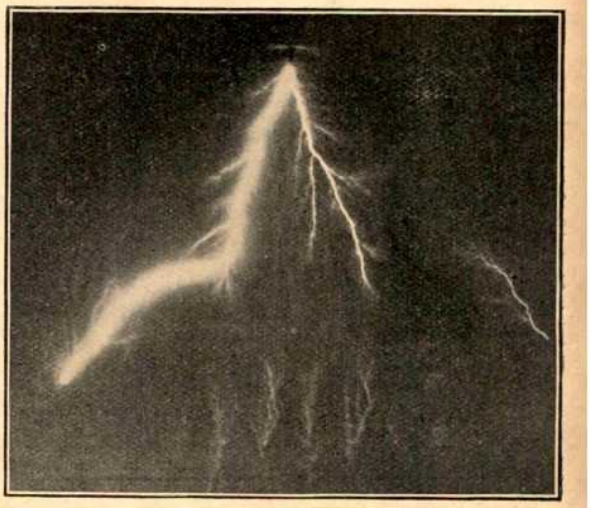

FIG. 2.

The conclusion that the branching criterion for cloud polarity is invalid seems unavoidable and is supported by the recent results of Lewis and Foust,[1] who have examined 100 cases in which lightning actually struck exposed conductors, and found that a negative charge was conveyed from cloud to ground in every case.

It is difficult to reconcile this negative branching with the common observations of positive and negative discharges. In addition to the observations on spark discharges mentioned above, the Lichtenberg figures taken between point and point or point and plane show that around the negative pole there extend straight radial streamers showing no branching, whereas around the positive pole the streamers are forked, and when a certain critical voltage is exceeded it is from the positive pole that heavy tree-like discharges extend far beyond the confined circle of brush discharge. What, then, are the conditions under which a positive discharge is suppressed and the negative enhanced so that in the macroscopic example of the lightning discharge the branching occurs from the negative pole?

One obvious difference between experiments in the laboratory and in the field is that in one case we are dealing with a symmetrical gap and in the other with an unsymmetrical gap. It is well known that the sparkover voltage of a point-plane gap is considerably less when the point is the positive pole than when it is the negative pole, whereas a sphere-sphere or point-point gap can show no such difference. But more important than this difference is the part played by the projections from the earth's surface—trees, buildings, etc.—which contribute their quota of space charge in the electric field between earth and cloud; these projections have not featured in experiments hitherto.

Some time ago, one of us had occasion to study the discharge of an impulse generator delivering 1,000,000 volts to a point-plane gap; it was noticed then that all positive impulses applied to the point—the plane being connected to earth—showed branching from the point; all negative impulses showed branching from the plane. Clearly asymmetry of the gap was insufficient to produce branching from the negative point. On raising a short projection out of the earthed plane, branching occurred from the high voltage point when positive, but in addition there was marked branching from the projection, that is, from the negative point. We have recently had further opportunity of continuing experiments on these lines; confining our attention to the case when the high voltage point was negative, we created a positive space charge above the plane by erecting from it a comb of short nails. From most of these proceeded short streamers branching upwards, whilst from the negative point the main discharge to ground was accompanied by many side branches forking downwards, as illustrated in Fig. 2. Negative corona is seen extending for a short distance from the electrode above the discharge, and positive branching is seen above the nails—St. Elmo's Fire. Thus, provided the conditions are correct, negative branching of a magnitude comparable with positive branching can be produced, and we have a ready explanation of the branched discharges from negative clouds. This throws fresh light on the mechanism of the discharge, and further investigations are proceeding.

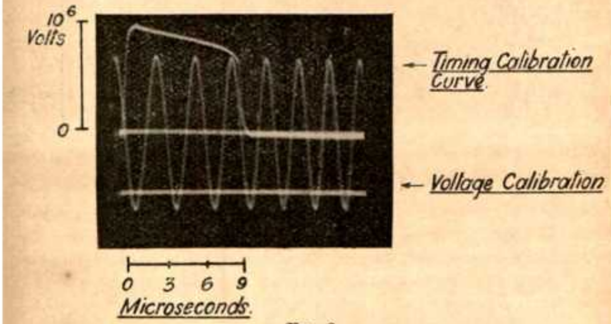

FIG. 3.

Fig. 3 is an oscillogram of the impulse applied to the point; the voltage applied reaches a maximum of 10^6 volts in ½ microsec., remains at that figure without oscillations for 9 microsec., and decays as the discharge passes to ground in ½ microsec. The polarity of the discharge is given by the oscillograms and also by a polarity indicator on the impulse generator. The current in the discharge is about 1000 amperes.

Some of the thunderstorm observations referred to are due to Mr. E. L. Halliday, of the University of the Witwatersrand, Johannesburg, whom we have to thank for permission to use them; our thanks are due to Mr. F. R. Perry and Mr. W. G. Hawley for assistance with the impulse generator, and to Mr. A. P. M. Fleming, for permission to publish.

Atoms and Molecules as Fitzgerald Oscillators.

In his studies on the polarisation of scattered radiations, Bhagavantam,[1] besides recording numerous cases in which the displaced lines in the spectrum of the light transversely scattered by liquids exhibit complete depolarisation, also discovered in the case of sulphur trioxide liquid an anomalously polarised line. The depolarisation of this line exceeded unity; in other words, the horizontal component, instead of being weaker, as in normally polarised lines, was actually stronger than the vertical component. Critical and systematic investigations undertaken by S. Venkateswaran definitely confirm the existence of such anomalous polarisation in the spectra of light-scattering by various organic liquids, and indicate that it is by no means an unusual phenomenon.

The maximum depolarisation which a rotating electric dipole or Hertzian doublet can yield is 6/7 or 3/4 according as the incident light is common or plane polarised. It would seem, therefore, that we have to seek in some new direction for an explanation of the large depolarisations and anomalous polarisations so frequently encountered in light-scattering. It is proposed in this note to put forward, with all reserve, the suggestion that an atom or molecule scattering light may, in certain cases, function as a Fitzgerald oscillator or magnetic doublet. As electrons and nuclei in atoms and molecules are known to possess magnetic moments, there is nothing inherently improbable in this idea, and it offers an immediate explanation of 'anomalous polarisation' in light-scattering. For what is 'normal' polarisation for an electric oscillator is 'anomalous' for a magnetic oscillator, and vice versa.

A test of this idea is furnished by working with *polarised* incident light, and finding how a variation of its plane of polarisation affects the intensity of the given line in the spectrum. The conditions for maximum and minimum intensity for a Fitzgerald oscillator are the reverse of what they would be for a Hertzian doublet, the intensity of the line being a maximum when the magnetic force instead of the electric vector in the incident light is perpendicular to the direction of observation, and a minimum in the converse case. Venkateswaran has found liquid thiophene to be an excellent example of a substance which simultaneously gives 'normally polarised', 'unpolarised', and 'anomalously polarised' lines, and is, therefore, very suitable for the experiments. Polarising the incident light, and varying its plane of polarisation, he has discovered that 'normally' polarised lines show maximum intensity, while 'anomalously' polarised lines give minimum intensity, and vice versa.

The hypothesis that atoms and molecules may function as magnetic oscillators appears, therefore, to receive support from experiment. It should be remarked, however, that anomalous polarisation may also be explained as due to radiation from electric quadrupoles.

The Jumping Negative Glow.

I first observed the jumping negative glow in December 1929, in 'I' type Osglim tubes of special design supplied by the Research Department of the General Electric Company; the effect was demonstrated to the Physical Society on Dec. 13, 1929, and at the Royal Institution soirée on Jan. 24 of this year.

Afterwards it was found that Taylor had observed a similar effect in a Beehive Osglim lamp filled with air.[1]

Investigations designed to throw some light on the cause of the phenomenon have been carried on at intervals during the past two years. In the course of these, it was observed some time ago that the jumping effect was produced in an experimental tube with sealing-wax joints when the wax was heated. This suggested that the phenomenon might be caused by impurities in the filling gas. A further series of experiments led to the conclusion that the introduction of minute quantities of the vapours of certain hydrocarbons (toluene and hexane were both found effective) would produce jumps in neon-filled tubes in which the negative glow was previously quite steady.

I hope that a full account of the experiments (which showed other interesting effects of the introduction of traces of hydrocarbon vapour into neon discharge tubes) will be published in due course.

The jumping negative glow is probably related to the wavering positive column in discharge tubes containing hydrocarbons, as demonstrated recently by the General Electric Company. W. A. LEYSHON.

Raman Spectra of Benzene and Toluene.

I HAVE during the last summer, at Macdonald Physical Laboratory, McGill University, examined the Raman spectra of benzene and toluene under the fairly high dispersion of 4·5 A. per mm. This work has revealed that the line in the neighbourhood of 1000 cm.$^{-1}$, always characteristic of the benzene ring, is complex.

In benzene there are five components :

1005·3 cm.$^{-1}$
998·8
992·2
983·9
980·3

In toluene there are four frequencies in this region :

1027·7 cm.$^{-1}$
1001·9
992·2
968·3

Several other lines are observed to be complex. In addition, a number of entirely new lines are observed in toluene. A complete account of the work will appear shortly in the *Canadian Journal of Research*.

LESLIE E. HOWLETT.

Ottawa, Sept. 28.

A New and Peculiar Marine Nemertean from the Australian Coast.

THIS note is to record the discovery of a rather anomalous nemertean worm from the coastal waters of New South Wales. The creature is of outstanding interest because its proboscis, that organ highly characteristic of the phylum, is apparently different altogether from any previously described for this group. In fact, we are not aware of any approximately similar protrusible organ having been recorded in any animal class.

The proboscis of the nemerteans usually consists of an introverted tube in a proboscis sheath, and it is everted like a finger of a glove that has been pulled 'outside in'. This new nemertean has also a proboscis which is retractile within a proboscis sheath, but the proboscis is branched. The branching is of the dichotomous type. By the help of the illustration (Fig. 1) the extraordinary nature of this organ will be realised. During eversion, which takes place almost explosively, the short main trunk first appears, then this divides and the finer and finer branches appear, but since each one of these is the result of an evagination the effect is almost indescribable. It is as if a large number of lively, wriggling, minute worms had been shot out. The tip of the animal is like a gorgon's head. The final branches, all tubular but quite thread-like, are constantly in motion, becoming now longer, now shorter.

If the stimulus has been great, there is, apparently, no possibility of the retraction of the mass and it is thrown off. But it is most interesting to watch the slow retraction which takes place when complete introversion occurs. Each fine branch inverts itself from the tip—rolls inwards—the branches become shorter until their point of origin is reached, and then the junction follows suit, invaginates, and so on.

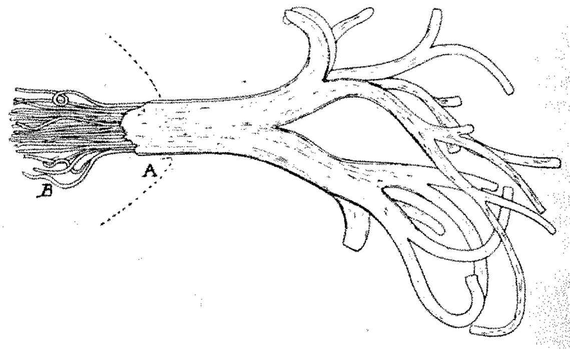

FIG. 1.—*Gorgonorhynchus repens* n.g. n.sp. Semi-extended proboscis torn away from the worm at A. At B can be seen the final branches of the proboscis not yet everted.

The illustration represents the result of tearing away from a worm the semi-extended proboscis. The primary and secondary branches have been everted but not the final ones, twenty or thereabouts in number, which lie within the former and still extend backwards. They have actually been exposed by the tearing away of the proboscis from the worm where its wall passes into that of the sheath.

A complete description of the anatomy of this interesting creature is being prepared. Many specimens have been found. The surprising thing is that such an anomalous form should fit in with one of the already known nemertean groups. From a study of its body wall it belongs to the *Heteronemertini*. We have created a new genus and species for it, *Gorgonorhynchus repens*, and the description here provided will serve to distinguish it from all other members of the group so far described.

Anisotropy Due to Flow in Cellulose Sols.

IT has been known for some years that certain liquids, and sols containing anisotropic colloidal particles, which in the normal state appear isotropic, will under the influence of external forces show some of the properties of anisotropic substances. The fact that an anisotropic state can be produced in certain fluids by means of the shearing forces caused by hydrodynamic flow, is due, at least in the case of sols, to the non-spherical particles contained in them.[1]

Cellulose gels have been shown to contain non-spherical colloidal particles or micelles,[2] and it is *a priori* almost certain that cellulose sols contain similar particles, which should be oriented by flow in just the same way as, for example, vanadium pentoxide sols are oriented. Further, since cellulose micelles show intrinsic optical anisotropy in the gel state, it should be possible to observe optical anisotropy in flowing cellulose sols.

In the case of cellulose nitrate sols in ether-alcohol, Kundt [3] has reported the generation of double refraction by shearing stresses, though he tried unsuccessfully to explain his observations as due to strains set up in the fluid. But since then an adequate explanation has been advanced, which ascribes the anisotropy to deformation and orientation of the particles.[4, 5] However, Faust [6] was not able to observe any anisotropy in flowing cellulose sols produced by the viscose process, and advanced the improbable theory that the anisotropy present in the fibres of artificial silk (generally regenerated cellulose gel) is due entirely to internal strains. Against this there is a large body of experimental evidence which indicates that this anisotropy is due to an oriented structure of the artificial silk fibres.[7, 8] Such an oriented structure must be originated in the sol from which the gel is produced, since it is not possible to produce permanent anisotropy in unoriented cellulose gels, by stressing them, of the same kind as that possessed by gels produced from rapidly flowing sols in the usual way.

On carrying out an investigation, I found that cellulose sols in cuprammonium hydroxide solution did show appreciable double refraction when flowing, thus indicating that they contain non-spherical particles which are capable of being oriented by flow.

Ageing in the case of vanadium pentoxide sols results in the growth of larger particles,[1, 5] which, other conditions remaining constant, are more easily oriented and thus give a greater double refraction. However, ageing of cellulose sols in the presence of air gave rise to lower double refraction, indicating a diminished particle size. This is to be expected, since the viscosity of such sols falls on exposure to air,[9] and this fall of viscosity is considered to be due to a decrease in micelle size.[10]

A fuller account of the anisotropy of cellulose sols when flowing, with particular reference to their behaviour during the spinning process in the manufacture of rayon, is to appear in the *Journal of the Society of Chemical Industry*. J. M. PRESTON.

The Oldoway Human Skeleton.

THE announcement by Mr. Leakey and his colleagues [1] that, in their considered opinion, the Oldoway human skeleton found by Prof. Hans Reck in Tanganyika Territory, in 1913, appears to be of late Kenya Chellean or Kenya Acheulean age, is of outstanding interest. The Oldoway remains represent, unquestionably, an individual of the type of *Homo sapiens* who was buried in the ultra-contracted posture. Moreover, while there may be some doubt whether it is yet possible exactly to correlate the Chellean and Acheulean periods of Kenya with the corresponding prehistoric phases of Europe and of Great Britain, it does not seem probable that there is any great difference in antiquity between them.

It is therefore apparent that, if Mr. Leakey and his colleagues are correct in their opinion, there is now to hand evidence that in Chellean or Acheulean times in Africa there was in existence a race of people who were of 'modern' type and buried their dead in the contracted posture. Though this may seem incredible to some, it is not so to those who, in view of the evidence furnished by certain skeletons of *Homo sapiens* type found in various parts of the Continent and in England in pre-Mousterian deposits, and judging by the excellence and skill with which flint implements of the Acheulean period were made, have concluded that human beings of a high type were living at that epoch.

Further, if Mr. Leakey and his colleagues are right in their estimate of the age of the Oldoway skeleton, it is necessary to conclude that the origin of man must date back to a time much more remote than has been generally imagined, and this will also confirm the opinion of those who believe, from a study of his flint and bone implements and other cultural relics, that man was already well advanced in the Pliocene period. In view of these considerations, all those interested in man's antiquity will look forward to the publication of the detailed evidence upon which Mr. Leakey and his colleagues have based their momentous conclusion.

Priestley and Lavoisier.

I SHOULD like to make one correction (due to my friend Dr. Meldrum) of a statement in my discourse on Priestley before the Royal Institution. On p. 25 of the discourse, I say that "In his memoir of 1775 Lavoisier does not refer to Priestley". I ought to have said that Lavoisier "does not refer to his meeting with Priestley in October 1774". This was the meeting following Priestley's famous experiment of Aug. 1, 1774, generally described as the 'discovery of oxygen'. Lavoisier does, as a matter of fact, refer at the end of his paper to Priestley's views on fixed air as a compound of ordinary air and phlogiston, which he says, though not without plausibility (*non sans vraisemblance*) are contradicted by the facts. The correction does not affect my general argument. P. J. HARTOG.

A New Locality for *Gammarus chevreuxi* Sexton.

IN the autumn of 1929 the dominant animal in the fauna of Wyken Slough, near Coventry, was a *Gammarus*, the species of which was uncertain, but which I then recorded as *G. pulex* Linn. I have since sent specimens to Mrs. Sexton, who has identified them as *G. chevreuxi* Sexton. This organism has previously been found only in Chelston meadows, near Plymouth, and in view of its value in the study of genetics a new locality is worth recording.

Wyken Slough is a pond of about five acres in area, of brackish water (salinity 8·3 parts per thousand), at Alderman's Green, Foleshill, about three miles north-north-east of Coventry, Warwickshire.

Research Items.

Human Remains from Kish.—Dr. L. H. Dudley Buxton and Mr. D. Talbot Rice have published in the *Journal of the Royal Anthropological Institute*, vol. 61, Jan.-June 1931, a report on human crania and skeletal remains from Kish collected by the Field Museum and Oxford University Expedition in the three seasons 1923–26. The material was excavated in the old Sumerian palace at Ingharra (Eastern Kish) and Mound *W*, and belongs to the period immediately preceding the age of Sargon of Agade. It is contemporary with the fourth and last dynasty of Kish (2900–2800 B.C.), of which the names indicate the Semitic character. Owing to the defective condition of the material the number of specimens available for study is relatively small. In the majority of cases the height of the head cannot be measured, and the series comprises twenty-five specimens only. Examination of the crania suggests a dichotomous classification, corresponding to the linguistic and cultural division into 'Semitic' and 'Sumerian'. The majority of the skulls are distinctly long-headed and usually high, the extra height being due to a well-marked scaphocephaly. Yet the jaws are small instead of large and powerful as among most scaphocephalous races. This type of skull from Kish is strongly reminiscent of the Combe Capelle skull. The forehead is retreating and the eyebrow ridges prominent, cheek-bones and nose broad. It belongs to the type which has been described as Eurafrican, and is of considerable antiquity, lingering on in remote parts from western Europe to North Africa, and it may be very early in Egypt. The second type is also dolichocephalic. The main distinction is in the contour, which is rounded, not angular. The eyebrow ridges are mainly absent, and the occiput specially prominent. There is no scaphocephaly and the skull is well filled. It is assigned to Elliot Smith's 'brown race'. The third type is only sparingly represented. It is brachycephalic, with a well-marked eyebrow ridge and a stronger jaw. There is little doubt that it is 'Armenoid'. It did not penetrate to Ur. In a similar series from Ur the first two races from Kish are present, but not the 'Armenoid'.

Migrations of the Greenland Whale and Narwhal.—In the *Geographical Journal* for September is a paper by Dr. R. W. Gray on the colour of the Greenland Sea and the migrations of the Greenland whale and narwhal, founded mainly on log-books of the whaling vessels *Eclipse* and *Hope*, belonging to his father and uncle, in the former of which he himself has sailed. Both species of cetaceans, it appears, avoid the clear blue water and congregate in that which is turbid and olive-green in colour owing to the presence of diatoms, which supply food to the copepod *Calanus finmarchicus*, on which the whale feeds. The cuttle-fish (which feed the narwhal) also, it is suggested, ultimately depend on these. The 'banks', or areas of green water, appear to drift, like the ice, south-west, and are accompanied by the cetaceans for a varying distance according to circumstances, when they turn and migrate north-east, as they had done originally to meet the 'banks' early in the year. Whales are much dependent on ice for shelter, and the introduction of steam has increased this tendency. In summer there seems to have been some separation of the tribes in both cetaceans, the males of the whale following the food-banks south-west, while the females and young went north: while some of the narwhals also take a northerly route, independently of sex. Narwhals have been practically untouched by whalers, but it is suggested that whole tribes of the whales, with resorts and routes of their own, have been killed off, or nearly so.

Disappearance of Insect-borne Diseases from Britain.—Dr. Ll. Lloyd contributed a paper on this subject before Section D (Zoology) of the British Association on Sept. 20. In commenting upon the fact that Britain has suffered in the past from such insect-borne diseases as bubonic plague, typhus, relapsing fever, and malaria, Dr. Lloyd discussed the possible causes responsible for their more recent absence. There appears to be no evidence of any graded climatic change to account for the improved state of affairs. In so far as plague is concerned, this disease was dependent on insanitary habits in towns and fragile houses, which, respectively, afforded food and shelter to the black rat and allowed it to multiply greatly. With changes in these conditions, enforced by legislation, the black rats were reduced in numbers and plague ceased. Rapid reduction in numbers of the human flea is still in progress. Typhus and relapsing fevers, which are louse-borne diseases, had their foci especially in gaols and insanitary camps, and, when these were reformed, continuance of these diseases was due to the vagabond class. Outbreaks followed especially after famines, and the ability of the British people, in recent times, to make up any deficiency of food by importation has been an important cause of their cessation. Social measures which have tended to reduce the condition of utter vagabondage also contributed. Malaria was widespread in England and Scotland up to 1800, and since then, in several outbreaks, a tendency to restriction of its northerly range is noted. It is suggested that an old strain of malaria, capable of transmission at a somewhat lower temperature than present-day strains, has died out, probably owing to very cold years. Other factors which have, or may have, played a part in the reduction of malaria are—better treatment of the disease; increased drainage through improved farming; possibly also a change in the feeding habits of *Anopheles*, such as Hackett and Missiroli believe has abolished malaria from parts of Italy.

Atlantic Foraminifera.—In the eighth and concluding part of J. A. Cushman's "Foraminifera of the Atlantic Ocean", the author describes the species which have occurred in the waters adjacent to the United States, including the Caribbean Sea (*Bull.* 104, Smithsonian Inst., 1931). Nine families are included in this account. From the Rotaliidæ, a large family, the geological history of which begins with the genus *Spirillina*, recorded as early as the Cambrian, developed the Amphisteginidæ, the palæozoic records of which are stated to be erroneous. The pelagic habit of many species of the Globorotaliidæ and their association with the Globigerinidæ in both recent and fossil marls and oozes are held to indicate the close relationship of the two families—the Globigerinidæ have developed from the Rotaliidæ as a specialised group adapted to pelagic conditions. The Anomalinidæ, another family derived from the Rotaliidæ, gave rise to the attached forms placed in the Homotremidæ, and to the Planorbulinidæ, the species of which are mostly in the Indo-Pacific at the present time, but were more widely distributed in the tertiary period. The paper is illustrated by twenty-six plates.

Leaf Fall in the Tropics.—Mr. R. E. Holttum has recently put on record (*The Gardens' Bulletin*, Straits Settlements, vol. 5, Nos. 7 and 8, June 1931) the behaviour as regards leaf-fall and flowering of a number of trees in Singapore, thus rendering comparison possible with the behaviour of similar trees in the more seasonal tropical climates of Java and Ceylon, on which Coster and Wright have previously made similar observations. The climate of Singapore is very uniform throughout the year, but there is usually a definite change to drier conditions after the north-east monsoon in February, and also some tendency for July and August to be comparatively dry. It is therefore interesting to note that trees of a number of deciduous species change their leaves annually about February, whilst a few species change their leaves in August, and four species were observed to change their leaves twice a year, usually in February and August. A number of other species change their leaves at approximately constant intervals, which, however, have no reference to the faint seasonal cycle, so that, though the intervals are equal in time, they have no reference to the annual cycle and fall upon different months in successive years. These trees, especially, show variation from tree to tree within the same species, and Holtum's observations, since 1927, have been based upon weekly observations upon the same individuals. Detailed notes are given upon the different species, and interesting comparisons with Wright's and Coster's observations are made.

Liquid Drops in Electric Fields.—The October number of the *Proceedings of the Royal Society* contains a paper by Dr. W. A. Macky on the behaviour of water drops in electric fields which clears up several points in connexion with the mechanism of thunderstorms. It appears that the first effect of an increasing field is simply to elongate a drop. Then, at a field strength which varies inversely as the square root of the initial radius, instability sets in and filaments of liquid are drawn out from both ends, accompanied by characteristic electric discharges from the points so formed. The fields necessary to produce instability are independent of the air pressure, unless this is so small that the field is only a little greater than is required for a discharge in absence of the drops. Applied to storms, these results afford strong support for the view that the discharge current is carried by ordinary gaseous ions and not by charged droplets. They show also that the field will rise to some ten kilovolts per cm. immediately before a discharge passes, and that when this occurs the largest drops present are unlikely to be greater than about 0·15 cm. in radius, larger ones being automatically reduced by the formation of filaments. Dr. Macky's paper is illustrated by some interesting photographs of distorted drops and discharges.

Diffraction of Electrons.—Two papers on the diffraction of electrons in gases, which cover a large range of experimental conditions and serve as a check on the approximations which have to be made in the theoretical treatment of the phenomenon, are described by F. L. Arnot and by E. C. Bullard and H. S. W. Massey in the October number of the *Proceedings of the Royal Society*. The results provide, qualitatively at least, further convincing evidence that the interactions of electrons and atoms which have been studied are capable of description as a wave effect, but it is apparent that much still remains to be done in the necessarily complicated theoretical treatment of what occurs. The main features—the effect of the atomic fields, polarisation of the atoms in the interaction, and the exchange of electrons between the beam and the atoms—are probably recognised, but in the treatment of all three, difficult calculations and approximations are involved, the validity of which must be tested by reference to an extensive set of experiments such as the present ones, and even these are still evidently not completely adequate. At the moment, it looks rather as if the value of the diffraction patterns in the investigation of molecular structure consists chiefly in the comparison of the interaction of electrons with systems of known and of unknown internal arrangement respectively, and in the investigation of progressively deeper parts of a system by the use of electrons of increasing energy. There is, however, a natural tendency to look for unique analysis of structure from a theoretical treatment of the diffraction due to any particular substance, without reference to other substances, and future work is likely to be directed both on such lines and towards the accumulation of more complete experimental data.

Lightning Phenomena.—In a communication to Section A of the British Association on Sept. 25, Dr. B. F. J. Schonland gave an interesting account of observations he has made during more than eighty thunder-storms. It is well known that an electric spark branches away from the positive pole of the discharger. It has also been observed that lightning discharges between the base of a cloud and the ground generally fork downwards, away from the cloud base. It is therefore sometimes concluded that the base of the thunder-cloud involved in such a flash is positively charged. Dr. Schonland described experiments made on South African thunder-clouds, which make it very difficult to accept this argument from analogy with the ordinary spark discharge. An examination of the results obtained from some 500 flashes showed that the base of the cloud was negatively charged in 98 per cent of the cases, although the branching was generally downwards. He exhibited records which show downward branches proceeding from the negative pole of the cloud. He gave evidence to show that the conditions preceding the ordinary spark gap discharge require modification before they can be compared with those prevailing below a thunder-cloud. When these modifications are made, the branching is no longer from the positive but from the negative side. The chief modification lies in earthing the positive side of the spark gap (see also p. 795 of this issue of NATURE).

The Dissociation of Water.—An investigation of the dissociation of water in the glow discharge, described by E. G. Linder in the *Physical Review* of Aug. 15, breaks new ground in the application of electrical methods to chemical problems. A tube was set up through which a continuous stream of vapour could be pumped whilst a discharge at a few hundred volts passed through it. The products of dissociation were collected and analysed, and at the same time the potential throughout the discharge and the concentration and energy of the electrons were found, wherever possible, by the use of probe wires. Further information about the electrons near the cathode was obtained by calculations based upon the recent satisfactory theories of the cathode dark space due to K. T. Compton and P. M. Morse. From the collected chemical and electrical data it was then possible to show that about 11 electron-volts were expended for each water molecule which was split into hydrogen and oxygen in the discharge, although the minimum energy needed is only 2·5 electron-volts, and that each electron in the negative end of the tube dissociated about five molecules. Further, the probability of dissociation by an electron near the anode was shown to be of a reasonable order of magnitude. Little information is given about intermediate products in the dissociation, but it is of interest in this connexion that Prof. Bonhoeffer, who has recently discussed a similar problem with T. G. Pearson in the *Zeitschrift für physikalische Chemie*, has shown that it is unlikely that the hydroxyl radicle can ever be isolated from the discharge, in spite of the intensity of its band-spectrum.

Microscopic Examination of Metals by Polarised Light.—In *Metallurgia*, Oct. 1931, p. 180, is given an account of work by Dr. M. v. Schwarz on the application of polarised light to metallographic investigations. Although suffering in parts from the translation, the paper will be of great interest, particularly perhaps to those concerned with non-ferrous alloys. As an example of the utility of the method may be mentioned the clear differentiation between cuprous oxide and sulphide in copper. The former under crossed nicols appears deep red; the latter, as well as the corresponding selenide and telluride, blue. Crystalline orientation is also very clearly differentiated, to such an extent that etching may in some cases be dispensed with altogether. In the examination of worked materials this is a matter of considerable importance, and the existence of 'preferred orientations' may readily be observed. Structures are in some cases—such, for example, as the ternary eutectic which occurs in certain high phosphorus-bearing bronzes—much more clearly revealed than by ordinary etching methods; and for the determination of the existence of small amounts of insoluble impurities the method may be of great scientific and industrial importance. Stannic oxide, for example, in bronze or in the corrosion product of the alloy, is very clearly revealed, and the characteristic, needle-like, idiomorphic crystals are very evident. Although an account of the necessary technique is given, it will probably be better to refer to the original account given by Reichert (*Zeit. für Metallkunde*, 17, 299; 1925).

Origins of Power Engineering.—In a short paper contributed to Section H (Anthropology) of the British Association on Sept. 29, Mr. H. P. Vowles gave a sketch of the origins of power engineering. For half a million years or more, man has sought to augment his own bodily power, first with sticks and stones which gave him the mechanical advantage of the lever and the wedge; then after a vast lapse of time, by means of simple mechanisms operated by man and animal power; and, finally, by an ever-increasing control over the forces of Nature. It is only during the past 7000 years we find any evidence of man's attempt to harness external power. One very early invention was the wheel and axle, which is found depicted on a Sumerian plaque of 5000 or 6000 years ago. The wheel and axle led to the use of the wheel for irrigation and flour milling. Water-raising wheels are of great antiquity, but before water-wheels could be adapted for driving mill-stones the toothed wheel had to be invented. Toothed wheels are referred to by Heron, Papus, and Vitruvius. Three primitive types of water-mill exist to-day. One of these, seen in China, consists of a pivoted beam, one end holding a pestle, the other end being scooped out as a water receptacle. Water flowing into the receptacle tilts the beam, raises the pestle, but spills the water, leading to the fall of the pestle. Another primitive mill has a vertical shaft with a horizontal wheel at the bottom placed in the stream, and another consists of a water-wheel with a lengthened axle bearing pegs which act as cams and raise stamps. Wind-mills came after water-mills, and probably some of the earliest were those in Seistan, Persia, a particularly windy region. Mr. Vowles has consulted all the important early writers who have referred to these things, and his paper concludes with notes on the earliest use of steam and the observations by the ancients on magnetic and electrical properties of materials.

Astronomical Topics.

Calendar Reform.—The *Times* for Oct. 31 contains an article on the Conference of the League of Nations that has been considering this question. It appears that the Conference confined itself to recommending a fixed Easter, and postponed all other suggestions of reform. The question of the date of Easter is primarily an ecclesiastical one; other authorities can do no more than make recommendations. A consideration of some weight is brought out in the *Times* article: in one case the rules for Easter deliberately postpone it for a week after the Passover—this is when the fourteenth day after the tabular new moon falls on a Sunday; Easter is kept a week later. A fixed Easter would generally be within a fortnight of the Passover, and the difference between a week and a fortnight does not appear to be a vital one. There are two points in the present secular calendar that are inconvenient in astronomical calculations: the absence of system in the lengths of the months, and the insertion of the leap-day at the end of the second month instead of at the end of the year. Regret will be felt that the Conference did not come to any decision on these matters.

Determination of the Mass of Triton, Neptune's Satellite.—A note in NATURE for Sept. 5, p. 416, gave a summary of the research on this mass made by Dr. Nicholson and Messrs. van Maanen and Willis, using photographs of Neptune taken near its stationary point with the 60-inch reflector at Mt. Wilson. Further details of the research are given in *Pubs. Astr. Soc. Pacific* for August 1931. It appears that the result given in the former note was not quite correct; the mass that they find for Triton is 0·06 of the earth's mass, with a probable error of 0·024. If two rather poor plates are excluded, the higher value 0·09 of the earth is obtained. Even the smaller value 0·06 would make Triton by far the most massive satellite in the solar system; it would be more massive than Mercury, and nearly five times the mass of the moon.

The early notice of this work issued in the *Science Service Bulletin* implied that it was hoped that the research might throw some light on the mass of Pluto. Presumably the idea was that if Triton was found to have a higher mass than would be inferred from its light, the same was likely to be the case with Pluto.

The Numbering of Minor Planets.—The numbering of new planets is assigned to the Berlin Rechen-Institut. No planet receives a permanent number until five accurate observations, extending over several weeks, are available. A considerable number of planets that do not come up to this standard in the year of discovery have provisional orbits calculated; these sometimes enable the planet to be recovered in a subsequent year, and it can then receive a number. *Circular No. 472* of the Institut, issued on Sept. 28, assigns numbers to 31 new planets; the last of these has the number 1183. Seventeen of the 31 have been observed at more than one opposition. Planet 1930 *SQ* receives the number 1170; it had been hoped that this planet would prove to be identical with 330 Adalberta, which has been missing since 1892, the year of its discovery. The identity has presumably been found untenable.

Some hundreds of planets, in addition to the 1183 numbered ones, have had approximate orbits deduced, but await reobservation before being definitely enrolled. The work of following the records of these small planets keeps the Rechen-Institut very busy; two or three circulars are issued every week.

The South African Association.

GRAHAMSTOWN MEETING.

THE twenty-ninth annual meeting of the South African Association for the Advancement of Science was held in Grahamstown on July 6–11, 1931, under the presidency of Prof. J. W. Bews. The meeting was very well attended and 109 papers were read. The South Africa Medal and grant were presented to Prof. H. B. Fantham at the close of the presidential address. A popular illustrated lecture was delivered by Prof. R. H. Compton on "National Parks". There was a reception by the mayor and councillors, and a whole-day excursion to Port Alfred.

The presidential address to all sections was given by Prof. J. W. Bews on "The Ecological Viewpoint", the substance of which appeared in NATURE of Aug. 15, p. 245.

The year's progress in astronomy formed the subject of Dr. H. L. Alden's presidential address to Section A. The effect of the discovery of Pluto on astronomical science was discussed and the conclusions so far reached as to its mass, reflecting power, and eccentric orbit. The close approach of Eros to the earth has led to observations on its apparent double nature, variations in brightness, apparent elongation or duplicity, and rotation of the elongation. The discovery at the Union Observatory of a variable star with a period of only 100 minutes was noted, with its possible great consequences on evolutionary developments. The occurrence of diffuse matter in space, its concentration in the plane of the Milky Way and the possible use of infra-red photography in connexion with it, and the measurement of the velocity of a distant spiral nebula were also considered.

The aims and objects of soil science formed the subject of the presidential address to Section B, given by Prof. I. de V. Malherbe. A review was given of the rise of soil science since the work of Sprengel, and special reference was made to the work of Russian scientific workers who laid the foundations of the science of pedology, devised new methods for its investigation, departed from traditional methods of analysis, and stressed the importance of the whole soil profile. The developments arising from soil profiles and soil horizons were noted. The climatic basis of soil classification was extended to other European countries and further developed by Hilgard for American soils. International soil congresses have become a feature in work on soil science, and have grown in importance and scope. The work of the six Commissions of the International Society of Soil Science was outlined, these covering soil physics and mechanics, soil chemistry, soil biology and biochemistry, plant physiological methods, soil genesis, nomenclature and mapping, and applications to soil technology. The need for research in soil science and establishment of fundamental principles for applied science were stressed.

Prof. N. J. G. Smith in his presidential address to Section C dealt with the problem of making conditions unsuited to infectious diseases (mainly illustrated from plant diseases). Environmental conditions for diseases being extremely varied, co-operation between different branches of science is possible in combating them. The parasitic fungi, bacteria and virus diseases can be controlled by making conditions uncomfortable and unsuitable for them. Sensitivity to environment was illustrated by consideration of fungal cultures, for example, day and night growths of *Helminthosporium* on barley, temperature and growth rate, the sensitivity to which promotes or hinders the spread of plant parasites, the great sensitivity of fungi to the chemical nature of their environment, associated with which was the phenomenon of 'staling' of the parasite, which, by its own activity,' produces chemical substances that stop its own growth. The possible application of these chemical substances by inoculation into plant tissues and of soil inoculation was indicated. The problem of keeping parasites at a distance was among the other topics discussed.

Dr. C. von Bonde discussed the correlation between marine biology and the problems of the fishing industry in his presidential address to Section D. The history of the Marine Biological Survey of South Africa was traced from its inception in 1895. In 1929 a new specially constructed survey ship was commissioned. In addition to investigation of the effect of trawling on the Agulhas Bank, further prolific trawlable areas have been found. Many other lines of work are in progress. These include intensive continuous study of the plankton and its fluctuations, seasonal variations in migration of fish, with their dependence on currents, salinity, phosphate and nitrate content of water, tagging experiments by special means for study of migration, scientific legislation with the view of conservation of supply. The fisheries survey work demands a complete biological and physical survey of every hydrographic basin and the whole coast of the Union, determination of life-histories of all animals and plants of economic importance and their associations, the physical and biological problems connected with artificial culture, an effective code of laws, schools for training fishery investigators and administrators, and the survey working in co-operation with the universities.

The presidential address to Section E, delivered by Mr. A. J. H. Goodwin, dealt with problems of association and chronology in prehistory. Speculation on prehistoric man's habits from man's physical and cultural remains was deplored. Association, chronology, and technology were stressed, also correlation with related branches of science. Simplicity is an ideal. Terminology and lax use of it has caused misunderstanding, and the use of such terms as culture and industry were therefore discussed. Cultural development, phases, and variations in South Africa are of some difficulty not experienced elsewhere. Phase is considered a change in fashion, variation a major cultural development brought about by a major force. The importance of association and some of its pitfalls were noted, also the difficulties due to muddled use of racial and cultural terms. The vexed question of patination and dating was discussed in general and with special reference to dating of petroglyphs. The desirability of correlation of chronological series from individual sites to provide generalised series for zones was emphasised.

"Intelligence, Environment, and Heredity" was the subject of Prof. R. W. Wilcocks's presidential address to Section F. The question of interaction of environment on heredity and vice versa was discussed in relation to intellectual efficiency. The many types of researches in connexion with the problem were outlined, such as correlations between blood relatives, estimate of intelligence of pupils by teachers, concomitant variations, correlation between intelligence of siblings and that found between various physical characters. The results of work on twins were considered. The literature relating to attempts to get correlations between environmental factors and intellectual efficiency was reviewed, the conclusion being that apparently marked changes and differences of environment do not affect intelligence quotients of children to any great extent. A brief mention of the South African Group Intelligence Tests results was made. The average I.Q. of 3281 'poor white' children of ages 120 to 155 months showed a definite tendency to sink with increase in chronological age, which is ascribed to unfavourable environmental conditions under which the 'poor white' child lives.

In Section A astronomers dealt with the cause of a nova outburst, second order terms in differential refraction in the measurement of photographic plates, comparison between observations on a comet and an ephemeris and the expanding universe. Meteorological papers were concerned with Rhodesian rainfall and the meteorite at M'Bozi, Tanganyika. Soil reclamation and water provision in arid countries were of much interest and the goodness of fit of Dieterici's equation was discussed. Engineers were interested in papers on induction heaters, electric current and the human body, and road construction and maintenance problems in South Africa. An interesting paper was contributed on the historic determinations of the longitude of the Cape.

In Section B papers of chemical interest dealt with the sugar-acid relationship in oranges, the essential oils of *Empleurum serrulatum*, the recent results of plant poison work, the value of valve potentiometers in physico-chemical work, and electrically heated vacuum desiccators. Accounts were given of the mineral springs of South Africa and of the register of medicinal waters of the country. Natural products of the Union such as Iceland spar and the clay responsible for the ceramic industry at Grahamstown were of interest, as was the paper on the products of native iron smelting. The nature and significance of the soil colloidal complex interested geologists and agriculturalists alike.

In Section C important papers on germination of wattle seeds, the germinating capacity of certain native South African seeds, on the vegetation of Natal, and on the siccation process were contributed. In systematic botany there were revisions of the genera *Lopholæna* and *Sutherlandia*, the evolutionary tendencies of the Labiatæ, new species of *Juncus*, and the parasitism of *Harveya*. Mycological papers dealt with new species of South African fungi, bacterial diseases of grain, physiological forms of *Puccinia graminis*, anthracnose of almonds, and new diseases of potatoes. Agricultural problems included studies in pasture management, grass or bush in the Karroid areas, physical properties of wattle soils, soil depletion, experiments on the control of *Selago*, and the fertility factor in turf production.

In Section D a number of interesting new parasitic Protozoa and the Protozoa from Kalahari soils were described. A series of papers dealt with various Amphibia from the points of view of morphology, osteology, and economics. The mammalian basicranial axis and the descent of the mammalian vomer from the reptilian parasphenoid were discussed. The embryological development of the beetle, *Euryope terminalis*, was described and beautifully illustrated. Methods of marking insects taken at regular intervals in quantitative samples, the therapeutic uses of detoxicated snake venom, and fish mortality were of interest. The native beliefs concerning pregnancy and child-birth, with their effects on public health administration, formed a useful practical contribution. A series of papers dealing with sheep and wool research, density and staple length, variation in the merino fibre, correlation between crimp and diameter of wool, and the blowfly menace were taken in a special sheep and wool subsection. Fine exhibits of small mammals from south-west Africa, of deep-sea fishes, of extinct mammals associated with the Taungs skull, and of curious letter-like markings on the mouth of a snoek were displayed.

In Section E an account was given of Bushman paintings at Quthing, Basutoland, and of the present-day Basuto copies of them, the skeletal remains of cave dwellers of the Outeniqua Mountains were described, and also skeletal material from early graves in the Riet River valley. The traces of Bushman occupation in Tanganyika Territory were detailed, and an interesting historical and philological investigation of the lost tribes of the Cape was given. Artefacts from Melkhoutboom and implements from Healdtown were described, also rock engravings and suggestions as to their significance and age. Superstitions of coloured people in Knysna and traditions connecting the Bantu and Zimbabwe were discussed, and a paper on native music dealt with the mystery of the Grand Gom-gom.

In Section F papers of much economic interest dealt with provincial councils from the point of view of political science, with indirect rule in Tanganyika, and with an analysis of the contributions to family support of women workers on the Witwatersrand. The quantitative valuation in ethics and the question of the retention of the distinction between sensation and perception were considered. Educationists were interested in investigations into intelligence tests in South Africa and in experiments in vocational guidance. Two papers of much historic interest dealt with the making of a Cape governor, Sir Benjamin D'Urban, and with early revenue and taxation in South Africa. Another most interesting paper dealt with the new cosmology in its historical aspect, Plato, Newton, and Whitehead being considered. An account of the International Institute of Intellectual Co-operation was given at a meeting of all sections.

The next annual meeting of the Association will be held at Durban in July 1932, under the presidency of Prof. P. J. du Toit. H. B. F.

Metallurgical Spectrum Analysis.

TWO papers on metallurgical spectrum analysis, presented at the recent meeting of the Institute of Metals at Zurich, "Application of the Spectrograph to the Analysis of Non-Ferrous Metals and Alloys", by H. W. Brownsdon and E. H. S. van Someren, and "The Spectrographic Assay of some Alloys of Lead", by D. M. Smith, represent the latest developments of a method of metallurgical analysis which appears to have been first suggested and used by W. A. Miller, assayer to the Mint, in 1863. The theory and technique of metallurgical spectrum analysis were elaborated by physicists having academic interests, but it is noteworthy that the present papers, and others recently published, emanate from the research departments of industrial concerns—Imperial Chemical Industries, Ltd. (Metals), and the British Non-Ferrous Metals Research Association; moreover, these papers indicate that spectrographic methods have been adopted for particular routine assays. Now that the importance of the presence of small quantities of foreign metals in alloys is appreciated, though in individual cases the quantitative relations may be quite unknown, it is customary for specifications to set rigorous limits for the content of these foreign metals permissible; limits which, in the absence of precise knowledge, are often very low. It is in the works control of the production of such alloys that the methods described in these papers are particularly valuable.

The method most favoured by these writers is the simplest available, and it is the one most capable of general works use, since the instrumental routine does not require a high degree of technical training in the operator: reading and interpreting the spectrograms requires more training. Direct visual comparison is made of the spectrogram of a standard alloy with the spectrogram of the alloy to be assayed. For the examination of brasses, the authors of the first paper use a pair of electrodes, the positive being pure copper, the negative being the sample to be assayed. Spectra of arcs of all the standard alloys are run in this way and photographed with the standardised routine, and from an examination of the spectrograms, tables are prepared showing the relation between the intensities of the lines of the metal being determined and neighbouring copper lines. An example is shown in the accompanying table.

MANGANESE IN BRASS.

Manganese Line.	2949.	4236.
Manganese, per cent		
0·01	*b.v.* < Cu 2858	
0·02	= Cu 2858	
0·04	> Cu 2858	
0·1	< Cu 2997	
0·2	< Cu 2883 = Cu 2997	
0·3	= Cu 2883 > Cu 2997	< Cu 4249
0·4	> Cu 2883	= Cu 4249
0·8	< Cu 2961	> Cu 4249
1·6	= Cu 2961	

b.v. signifies barely visible.

The spectrogram of the sample to be assayed is taken with the same routine, and by a comparison of the intensities of the manganese line 2949 with the copper lines 2858, 2883, 2961, and 2997, and of 4236 manganese with 4249 copper, the manganese content of the brass is determined.

For the examination of lead alloys, a high tension spark discharge was used, both electrodes being of the metal examined. Relative intensity tables were prepared, in which the pairs of lines to be compared consisted of one line of the metal to be determined and a neighbouring lead line, but were otherwise similar to Table 1.

Preliminary experiment must be made to determine whether arc or spark excitation shall be used, what the arc or spark gap shall be, whether a condensing lens is to be used, and to standardise carefully the electrical conditions of the excitation and the photographic technique. It is evident from the papers under review and others recently published that different workers evolve different routines to suit their particular problems and equipment. Such papers as the present ones are valuable in that they give complete working details for the determinations of which they treat, as shown in the following table.

Alloy.	Metal determined.	Percentage range for which data are available.	
Brass . .	Lead	0·005	5·0
	Tin	0·005	1·3
	Iron	0·005	1·2
	Nickel	0·01	15·0
	Aluminium	0·01	2·0
	Manganese	0·01	1·6
Lead alloys	Tin	0·002	9·0
	Antimony	0·03	15·0
	Cadmium	0·0001	1·0
	Arsenic	0·03	1·5
	Bismuth	0·0003	0·15
	Copper	0·0002	0·06
	Zinc	0·001	0·06
	Silver	0·0006	0·002
	Thallium	Data for	0·001
	Mercury	Data for	0·005

In some cases these figures do not represent the extreme limits over which the methods can be used, but those which the writers have used in practice. When most of the observations will involve very small quantities, a modified procedure with longer exposure and development will be used; while for determinations which are mostly more than one per cent, it will often be advantageous to use the logarithmic wedge sector referred to later.

D. M. Smith deals, further, with the preparation of standard alloys, an important preliminary to putting a spectrographic routine into works operation; and with a more refined method of making the intensity comparisons. A simple spectro-photometer, the logarithmic wedge sector of Scheibe and Neuhäusser, is used: its use gives not so much an increased accuracy as an extension upwards of the range over which the equipment may be used for making determinations.

The accuracy to be obtained from both these methods is about ten per cent of the amount of the constituent present, over the range for which the method is applicable. Thus 0·1 per cent would be returned as between 0·09 and 0·11 per cent; 10 per cent would be returned as between 9 and 11 per cent.

A. A. FITCH.

Work of the Radium Commission.

THE first Annual Report of the work of the Radium Commission, published this time last year, gave an outline of the policy of the Commission, and stated that the radium was to be used primarily for the treatment of malignant disease. In the first instance, the faculties of medicine at universities throughout Great Britain, excluding Oxford and Cambridge, were approached, and negotiations with centres in London were made irrespective of the University.

The second Annual Report, just published,* shows that the year has been largely occupied in developing the work at the national radium centres. Since the Commission's scheme was launched, a number of medically qualified men have taken up radium therapy and by courses of study in England and abroad have prepared themselves for the position of radium officers. The wisdom of the policy of concentration of radium therapy at centres where the work can be properly organised can scarcely be doubted, for it is becoming generally recognised that this is a highly specialised kind of treatment, and to carry it out satisfactorily there has to be a certain amount of co-ordination; pure medicine, surgery, radiology, pathology, and physics all play their parts. In these circumstances, it is obvious that the best treatment can only be procured where there is a real appreciation of the many factors that should decide and control the exact methods to be adopted.

It has been necessary to enlarge on the original scope of this radium service, for owing to the uneven geographical distribution of the universities with medical schools where the twelve national radium centres had been established, it became obvious that there were considerable areas in England which could not be adequately covered by them. It is likely, in the near future, that regional radium centres will be established to serve these areas, the main policy of concentration at centres adequately staffed and equipped still being preserved.

---

* Second Annual Report of the Radium Commission. Pp. 32. (London: H.M. Stationery Office, 1931.) 6*d*.

The chief aim of the Commission for the first five years of its existence is not only to get the best facilities for radium treatment at these recognised centres, but also to be able to assess quantitatively at the end of this time exactly what the value of the radium has been in the treatment of cancer. All the centres keep their clinical records on forms which have been devised and issued by the Commission, and the information from these forms is to be collected yearly and assembled on statistical cards, the general form of which has been agreed upon in consultation with Prof. Major Greenwood. In this way it should be possible year by year to obtain information of the number of people treated, the various sites of cancer which have been treated, all technical details of the treatment, and progress of the patients.

Reference is made in the Report to the work at the Westminster Hospital with what is known as the 'four gramme bomb'. The trial with this appliance was limited in the first instance to cases of malignant disease originating in the breast, stomach, and prostate, and after a period of more than a year the conclusion has been reached that, under present conditions, this form of therapy cannot be recommended for the treatment of cancer in these regions. The Commission takes the view that surface treatment with radium may be better developed by dividing the bomb into smaller units.

Under the terms of its charter, the Commission has two main obligations imposed upon it in administering the national radium; and whilst it has considered that its most pressing duty is to "promote the treatment of the sick throughout Great Britain", it has also taken steps to forward the "advancement of knowledge of the best methods of rendering such treatment". With this latter object in view, it has allocated 1 gm. of radium element to the Medical Research Council and 0·18 gm. to the National Physical Laboratory. The policy of making such allocations to large corporate bodies in touch with individuals specially qualified to conduct the kinds of research work involved obviously has many advantages. As stated in the present Report, it is an encouraging sign of the activity of experimental research in radium that within a few months of completing the arrangements with the Medical Research Council ninety-five per cent of the loaned radium had been allocated to research groups.

Human Embryology.

OCCASIONALLY children are born with the terminal part of an arm or leg represented by a mere rudiment, or a whole segment may be missing as if an amputation had been performed within the uterus. Dr. George Streeter, director of the Carnegie Laboratory of Embryology, has made an important addition to our knowledge of such abnormalities (*Contributions to Embryology*, 1930, vol. 22, pp. 3-46). Having numerous examples of such abnormalities at his disposal, he has been able to throw light on many points which have hitherto been obscure.

It has usually been supposed that fibrous bands—known as amniotic bands—formed round the growing limb of the fœtus, causing a constriction, ultimately led to the death and shedding of the distal part of the limb. Dr. Streeter's investigations throw a new light on these encircling bands. They are not formed from the amnion but are developed as fibrous rings from the tissues of the necrosing limb. A survey of the evidence collected and tabulated by Dr. Streeter leaves no doubt in the medical mind that intra-uterine amputations are the result of a partial failure of the placental circulation, which leads to gangrene of the fœtal limbs—just as a partial failure of circulation in the adult may lead to gangrene of the extremities.

Fœtal tissues react to lack of blood quite differently from adult tissues. At the zone where separation is to take place between the living and dead parts of the fœtal limb, the lymph thrown out becomes organised and forms the constricting rings of tissue, known as 'amniotic bands'. The unnourished segment of the limb, being bathed in amniotic fluid, undergoes only partial death, parts of it surviving to form an irregularly shaped hand or foot.

Curiously enough, liability to intra-uterine amputation has been shown to be inherited in a few instances.

In the same volume, Dr. R. H. Hunter clears up certain obscurities relating to the development of the human vagina and hymen. In the sixth week of development the vagina is represented by a canal formed out of the fused lower ends of the Mullerian ducts. Thereafter the canal becomes represented by a cord of epithelial cells, this cord, which represents the vagina, continuing to elongate until the end of the fourth month. In the fifth month of development, the solid core of vaginal epithelium begins to proliferate rapidly on all sides, distending the canal round the corner of the uterus at the upper end and pressing against the wall of the vulva (urogenital sinus) at the lower end. The central cells degenerate and the lumen of the vagina is thus formed. The hymen, which represents part of the wall of the urogenital sinus, is formed out of the vagina-vulvar junction by the expansion of the lower end of the vaginal cord. The phylogenetic significance of these vaginal changes is still unexplained.

University and Educational Intelligence.

BELFAST.—Dr. J. S. Young, lecturer in experimental pathology and assistant director of cancer research in the University of Leeds, has been appointed Musgrave professor of pathology.

CAMBRIDGE.—Mr. A. G. Brighton (Christ's College) has been appointed curator of the Sedgwick Museum of Geology.

The Council of the Senate recommends that the Goldsmiths' readership in metallurgy be discontinued, and that a Goldsmiths' professorship in metallurgy be established, with a stipend of £1200 a year. The General Board recommends that a new faculty of geography and geology be instituted in the University. This faculty would include the Departments of Geology, Mineralogy and Petrology, Geography, Geodesy, and Geophysics.

At Emmanuel College, Prof. C. E. Tilley, professor of mineralogy and petrology, has been elected to a professorial fellowship.

V. V. Narlikar (Fitzwilliam House) has been elected to an Isaac Newton studentship, and H. R. Hulme (Gonville and Caius College) has been elected to an additional Isaac Newton studentship.

LONDON.—Dr. F. C. Benham, Sir Ernest Cassel lecturer in commerce at the London School of Economics, has been appointed University reader in commerce, and Mr. R. J. V. Pulvertaft, pathologist at St. Thomas's Hospital, has been appointed University reader in pathology (Westminster Hospital Medical School). The title of reader has been conferred on Dr. Nora Edkins, lecturer in physiology at Bedford College.

Applications are invited by the Royal Society for the Moseley research studentship, value £350, for the furtherance of experimental research in pathology, physics, and chemistry, and other branches of science, but not in pure mathematics or astronomy. Applications must be made by Dec. 15, upon a special form, to the Assistant Secretary, Royal Society, Burlington House, W.1.

At the recent general parliamentary election, besides those members for university constituencies who were returned unopposed, as announced in Nature for Oct. 24, p. 732, the following candidates have been elected: University of London, Sir Ernest Graham-Little; Combined English Universities, Miss E. Rathbone and Sir Reginald H. Craddock; University of Wales, Mr. Ernest Evans.

The award of the John Gray Jubilee Scholarship has just been made to Mr. G. Alan Thompson, a research student of the Gas Engineering Department of the University of Leeds. This scholarship was endowed by Mr. John Gray, a past-president of the Society of Chemical Industry, on the occasion of the celebration of the jubilee of the Society this year. It is tenable at such place of learning as the council or president may prescribe, and preference will be given to students who have already graduated in a university and are sons of members of the Society of ten years' standing.

Birthdays and Research Centres.

Nov. 10, 1861.—Dr. Robert T. A. Innes, Union Astronomer emeritus, Johannesburg.

At present I am working on the motion of the 12-year periodical comet 1927 *f*. I am also trying to find further grounds for the hypothesis that changes in the earth's climate are in the main due to impacts with the comæ of comets, and am examining and making further applications of Cowell's process to the motions of the major planets.

Nov. 12, 1863.—Prof. Alfred W. Porter, F.R.S., emeritus professor of physics in the University of London.

The work on which I have expended most effort during the last few years is divisible into several parts. (1) The calculation of surface tensions from experimental measurements on the ascent of liquids in tubes and by the bubble method. The part played by the angle of contact in the latter method is still a subject for discussion, though something has been done to clear the ground. For the tube method, I have given diagrams enabling the effect of the contact-angle to be allowed for (when it does not exceed 35°) with an accuracy surpassing that required in practice. (2) The interpretation of the Joule-Thomson effect, especially in regard to steam and to refrigerating materials. (3) The vapour pressures of binary and ternary mixtures. (4) The variation of the viscosity of colloids with shear. (5) The resolving power of optical instruments. Some work has been published on all these problems; further work is being more or less slowly elaborated, especially in regard to the Joule-Thomson effect.

Societies and Academies.

London.

Royal Society, Nov. 5.—Sir F. Gowland Hopkins and K. A. C. Elliott: The relation of glutathione to cell respiration with special reference to hepatic tissue. The relative capacity of various mammalian tissues to reduce the disulphide form of glutathione under anaerobic conditions has been determined. The course of the oxidation of the thiol group during the survival respiration of the hepatic tissue of various animals has been followed. That the concentration of certain metabolites in the liver is wholly, or in part, responsible for the maintenance and amount of reduction is shown by the effects of administering or withholding food. In general the initial marked delay in the disappearance of the $-SH$ group during aeration is observed only in the liver of well-fed animals; after relatively brief periods of fasting it is much lessened and may not be observed. If extra glutathione in the disulphide form be added to the freshly excised tissue before aeration, the existence of residual active hydrogen is revealed. In spite of vigorous aeration the concentration of $-SH$ then rises during the earlier periods of survival, though ultimately the whole is oxidised. The amount of this extra pressure-head of hydrogen consistently differs in the livers of different species. The origin of the active hydrogen which reduces the disulphide grouping is at present unknown. The transport of hydrogen to molecular oxygen by the path in question, though representing but a small part of the total respiration, may, therefore, prove to represent a specialised and significant aspect of tissue oxidations.—**Lord Rutherford and C. D. Ellis:** The origin of γ-rays. Calculations are made of the probability of escape of the α-particles from radium C' and of the average time of transition of the α-particle for different energies of the γ-ray. The strongest α-ray group, which corresponds to the emission of a β- or γ-ray of energy $1 \cdot 426 \times 10^6$ volts, represents an abnormal mode of transition compared with other groups. The time of transition is very long, and it may be, as suggested by R. H. Fowler, that the transition is radiationless, the surplus energy being directly transferred to one or more of the outer electrons of the atom. Many of the lines in the β-ray spectrum may be a result of similar radiationless transitions. In explanation of the complicated γ-ray spectrum of radium C' it is suggested that more than one α-particle in the nucleus may occupy the same energy level.—**A. V. Hill:** Myothermic experiments on the frog's gastrocnemius. An arrangement is described by which the 'initial' heat set free in the contraction of a frog's gastrocnemius can be measured in absolute units. A single fine thermocouple of constantan-iron is employed, the 'hot' junction lying inside the muscle. It may be applied to single twitches, to groups of twitches, or to tetani up to 25 seconds in duration. The mean value of Tl/H, the isometric heat coefficient in a twitch, is 13·4. This is twice the mean value found in sartorii. The difference is due to the fact that in gastrocnemii the fibres, or parallel fibre bundles, run, on the average, only half the length of the muscle. A modification is described of the method recently suggested by Bozler of 'calibrating' by condenser discharges. This is far simpler and more accurate than the old method employing an alternating current. The specific heats of muscle and blood have been determined. For a given water content they are the same. The density of a tissue depends upon the amount of solid it contains. This provides a simple and accurate method of measuring, without the labour of drying and weighing, the percentage of solid in a muscle.

Paris.

Academy of Sciences.—Sept. 28.—**Ernest Esclangon**: The observation of the eclipse of the moon of Sept. 26, 1931, made in Haute-Provence. The atmospheric conditions were exceptionally favourable. The most striking feature of the eclipse was the marked difference in the coloration and intensity of the earth's shadow, as a function of the distance from the centre of the shadow.—**E. Mathias** and **G. Grenet**: The electric field at the summit of the Puy de Dôme. A Benndorf recording electrometer has been set up in the dwelling-house, and the coefficient for converting these readings into those given at the summit (1440 metres) determined. A table showing the diurnal variation is given.—**Lucien Daniel**: The hybrids of the annual sunflower grafted on the Jerusalem artichoke. Grafting, in certain cases, is a factor capable of producing new variations.—**M. Ghermanesco**: The n-metaharmonic functions.—**Walter Saxer**: Families of meromorph functions of several variables.—**Henri Poncin**: The movement of a fluid round a cavitation.—**H. Mémery**: Some remarks on the duration of the solar period.—**L. Goldstein**: The intensity distribution in the continuous bands of the spectrum of hydrogen.—**W. Swietoslawski**: A new boiling-point method for studying ternary heteroazeotropes.—**E. Carrière** and **Janssens**: The determination of fluorine as calcium fluoride. Reply to a criticism of P. Maugnaud. Experiments on the magnitude of the possible error in the results caused by the co-precipitation of calcium carbonate with the calcium fluoride. It is shown that the error due to this cause is negligible.—**Georges Bohn** and **Mme. Anna Drzewina**: The influence of metallic silver on the calcification of the larvæ of the sea-urchin. If into water containing young sea-urchin gastrulæ a very thin sheet of silver is inserted for a time less than one minute, the pluteus has no skeleton and the calcification is prevented as long as the water remains unchanged. But if a trace of amino-acid is added along with the silver, the calcification proceeds normally.—**Paul Wintrebert**: The contractility of embryo cells, producing shape, a necessary factor in development, in amphibians.

Rome.

Royal National Academy of the Lincei, April 26.—**S. Pincherle**: A special linear operator.—**F. Conforto**: Mathematical formalism in a continuous functional space ruled by a linear element of the second species.—**R. Caccioppoli**: A method of summation in the calculation of infinite matrices.—**M. Villa**: The singularity of the Jacobian of $(r+1)$ hyper-surfaces of space of r dimensions.—**N. Cioranescu**: The summation of trigonometric series.—**P. Mentré**: The differential forms of a complex of straight lines.—**A. de Mira Fernandes**: Concurrent directions.—**Luca Teodoriu**: The zeros of the derivatives of a holomorph function.—**D. Bonvicini**: Certain fundamental theorems of electrodynamics and of the statics of elastic solids (2). Thermodynamical theorems corresponding with Castigliano's theorem, with Volterra's theorem of reciprocity, and with Colonnetti's second principle of reciprocity are enunciated.—**G. Valle**: Experimental investigations on the flash discharge. In experiments on the passage of electricity through rarefied gases, the course of the static characteristics in the various types of stationary régime of the flash discharge and the maximum value reached by the current intensity at the beginning of the discharge have been investigated.—**B. Rossi**: Absorption and diffusion of the penetrating corpuscular radiation in lead and iron. This radiation is diminished in intensity by 23·2 ± 1·6 per cent on passage through a screen of lead 9 cm. in thickness, and by 21·7 ± 1·6 per cent by a screen of iron 11 cm. thick, which contains an equal number of electrons per square centimetre. Diffusion is found to be of secondary importance and incapable of affecting appreciably the form of the absorption curve. Both the above values are distinctly lower than those obtained by Steinke (1930), the former being in good agreement with the value, 24·6 per cent, given by Bothe and Kolhorster (1929) for the absorption by a layer of gold 4·1 cm. thick.—**Algeri Marino**: Conditions of equilibrium in a Wheatstone bridge for measuring audio and radio frequency.—**L. Sanzo** and **F. Pirrone**: Irradiation of sea water by ultra-violet rays and its action on the velocity of alcoholic fermentation of glucose solutions. Further experiments show that the irradiated sea water activates alcoholic fermentation only if the period during which the water is exposed to the rays does not exceed a certain value, this being three hours under the conditions employed. The activity is due partly to the sea water considered as a solution of certain salts in certain proportions, and partly to an undetermined factor, which loses its effect if the sea water is either boiled for twenty minutes or evaporated to dryness and made up to the original volume with sterile distilled water.—**S. Sorrentino**: Mount La Queglia in Abruzzo. The geological formation of this mountain is described.—**V. Rivera**: Factors exciting increase of vegetal neoplasms by *B. tumefaciens*. In the experiments described, pelargoniums inoculated with the bacterium were completely encased in either hermetically sealed leaden sheaths or wooden sheaths lined with black paper. The plants enclosed in wood developed slight neoplastic formations at the zone of inoculation, whereas those in lead developed such formations to a greatly enhanced extent and formed also a number of aerial roots with positively geotropic development. The difference in behaviour in the two cases is ascribed mainly to the different humidity of the air. The phenomena are influenced also by the absence of light and by the ionisation of the air.—**R. Perotti**: Mycobacteriosis.—**C. Gaureschi**: The otocysts of urodele amphibia form a mosaic system (experimental demonstration).

Sydney.

Royal Society of New South Wales, Aug. 5.—**R. T. Baker**: On a fossil timber from the Sydney Harbour Colliery. The fossil was 20 ft. long and was taken from a depth of 2225 feet. The anatomical structure was very well preserved, which enabled it to be placed systematically as a conifer, resembling the genus *Callitris*. Its greatest affinity was with *Antarcticonyton Priestleyi*, Seward, found by the second Scott expedition, and so was named *A. Raei*. Calcium carbonate was thickly deposited on the cold-weather side of the tree, and also in numerous channels throughout the wood structure.—**W. R. Browne**: Notes on bathyliths and some of their implications. The division into synchronous and subsequent bathyliths is emphasised, the main contrasting characters of the two types are enumerated, and examples from Australia are described. The underground extensions and the probable shapes of bathyliths are discussed, and explanations are suggested for the association of synchronous bathyliths with strongly-folded and with subsequent moderately folded strata. Some stratigraphical and palæogeographical implications of bathyliths are pointed out. Since it was injected in connexion with the collapse of a geosyncline, the existence of an outcropping bathylith of determinable geological age implies the former existence, above and around it, of sediments belonging to a certain geological period. The use of this principle is exemplified in its application to a few Australian palæogeographical problems.

Diary of Societies.

FRIDAY, NOVEMBER 6.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 10.30 A.M.—N. Patterson: The Training of an Oto-laryngologist (Presidential Address).—E. W. Williams: Treatment of Suppurative Meningitis.—Dr. D. McKenzie: Some Graphs Illustrating Otosclerosis.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 5.

PHYSICAL SOCIETY (at Imperial College of Science), at 5.—Sir Arthur Eddington: The Expanding Universe (Presidential Address).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Demonstration of Specimens illustrating the Pathology of Hydrocephaly.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Ll. B. Atkinson: The Mechanical Aspects of Electricity (Thomas Hawksley Lecture).

SOCIETY OF CHEMICAL INDUSTRY (Manchester Section) (jointly with Manchester Sections of Society of Dyers and Colourists, Institute of Chemistry, and Chemical Section of Manchester Literary and Philosophical Society) (at College of Technology, Manchester), at 7.—Prof. H. Mark: The Significance of the New Cellulose Models (Molecular Structure) for the Technical and Dyeing Properties of the Fibre.

INSTITUTION OF ELECTRICAL ENGINEERS (Meter and Instrument Section), at 7.—F. C. Knowles: Inaugural Address.

SOCIETY OF CHEMICAL INDUSTRY (Newcastle-upon-Tyne Section) (at Armstrong College, Newcastle-upon-Tyne), at 7.30.—Prof. G. T. Morgan: Chemistry of Low-Temperature Tars (Jubilee Memorial Lecture).

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (jointly with South Wales Institute of Chemistry) (at Thomas' Cafe, Swansea), at 7.30.—Dr. Sladden: Chemistry in the Service of the Doctor.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—A. P. Quarrell: The Cooling of the Crude Oil Engine.

OIL AND COLOUR CHEMISTS' ASSOCIATION (Manchester Section) (at Royal Institution, Liverpool), at 7.30.—N. Heaton: Modern Developments of Inorganic Pigments.

ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Dr. H. W. Featherstone, J. D. Morgan, and others: Discussion on Anæsthesia for Diathermy and Endoscopy.

SATURDAY, NOVEMBER 7.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—F. E. Yerbury: Present-Day Architecture on the Continent (1): Modern Buildings in Holland.

GILBERT WHITE FELLOWSHIP (at 6 Queen Square. W.C.1), at 3.—W. B. Gourlay: Plant and Animal Collecting in Chili (Lecture).

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Section—London) (Informal Meeting), at 6.45.—Debate on: That a College Education is Desirable in the Training of a Mechanical Engineer.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Tees-Side Branch—Graduate Section) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—J. Lang: Chairman's Address.

MONDAY, NOVEMBER 9.

ROYAL GEOGRAPHICAL SOCIETY, at 5—Brig. H. L. L. Winterbotham: The Small-scale Maps of the Ordnance Survey.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—R. Davies-Colley: Demonstration on The Border-line Tumours of Bone.

INSTITUTE OF TRANSPORT (Annual General Meeting) (at Institution of Electrical Engineers), at 5.30.—J. Paterson: The Influence of Transport on Regional Planning.

ROYAL AERONAUTICAL SOCIETY (at Film House, Wardour Street, W.1), at 6.30—Capt. W. J. McDonough: Aeroplanes as an Aid to Mineral Exploration and the Operation of Aircraft in Sub-zero Temperatures.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—J. F. Shipley and others: Discussion on Lightning Protection, especially in Tropical Countries.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—R. Grierson: The Electrical Heating of Buildings.

CERAMIC SOCIETY (Pottery Section) (at North Staffordshire Technical College, Stoke-on-Trent), at 7.30.—T. Sheppard: Roman Pottery Kilns at Throlum.

INSTITUTE OF METALS (Scottish Local Section) (at 39 Elmbank Crescent, Glasgow), at 7 30—W. L. Govier: Experiences with Some Electric Furnaces for Melting Copper and Copper Alloys.

CAMBRIDGE PHILOSOPHICAL SOCIETY (in Botany School, Cambridge), at 8.45.—J. Gray: Animal Movements (Illustrated by Cinematograph Films).

INSTITUTION OF ELECTRICAL ENGINEERS (Western Centre) (at Technical College, Gloucester).—E. W. Dickinson and H. W. Grimmitt The Design of a Distribution System in a Rural Area.

TUESDAY, NOVEMBER 10.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. G. I. Finch: The Combustion of Gases in Electric Discharges (2).

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.—I. A. J. Duff: The Dilution Theory of Detonation.

Institute of Marine Engineers, at 6.—J. L. Adam: Effects of Propelling Machinery on Hull Structures.

Institute of Metals (Swansea Local Section) (at Y.M.C.A., Swansea), at 6 15.—Prof. D. Hanson: Some Causes of Unsoundness in Non-Ferrous Alloys.

Textile Institute (London Section) (at Clothworkers' Hall), at 6 30.—Dr. J. B. Speakman: Recent Developments in the Study of Wool Finishing Processes.

Institution of Electrical Engineers (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—R. Grierson: The Electrical Heating of Buildings.

Institution of Electrical Engineers (North-Western Centre) (at Engineers' Club, Manchester), at 7.—R. M. Charley: Recent Progress in Large Transformers.—W. E. M. Ayres: The Application of the Induction Voltage Regulator.

Institution of Electrical Engineers (Tees-Side Sub-Centre) (at Cleveland Technical Institute, Middlesbrough), at 7.—Dr. A. F. Burstall: Electric Welding.

Institution of Heating and Ventilating Engineers (Associate Members' and Graduates' Section—London and District Branch) (at Borough Polytechnic), at 7.—T. G. Noble: Notes on Ventilation.

Institution of Heating and Ventilating Engineers (Associate Members' and Graduates' Section—Manchester and District Branch) (at Engineers' Club, Manchester), at 7.—W. P. Ollett: A Summary of Modern Heating Systems.

Institution of Electrical Engineers (Scottish Centre) (at 39 Elmbank Crescent, Glasgow), at 7.30.—E. W. Dickinson and H. W. Grimmitt: The Design of a Distribution System in a Rural Area.

Institution of Automobile Engineers (Coventry Centre) (at King's Head Hotel, Coventry), at 7.30.—B. G. Robbins: The Training of Young Automobile Engineers.

Institute of Metals (North-East Coast Local Section) (at Armstrong College, Newcastle-upon-Tyne), at 7.30.—A. H. Mundey: Die-Casting.

Quekett Microscopical Club (at 11 Chandos Street, W.1), at 7.30.—Dr. Isabella Gordon. Reversal of Sex in Crustacea.

Institution of Welding Engineers (North-Western Branch) (at College of Technology, Manchester), at 7.30.—A. Y. Stirrat: Carbon Arc Welding.

Royal Society of Medicine (Psychiatry Section), at 8 30.—Dr. Bernard Hart: Psychology and Psychiatry (Presidential Address).

Pharmaceutical Society of Great Britain, at 8.30.—Sir William Willcox: The Practical Relationship of Bacteriology to Pharmacy and its Influence on the Curriculum.

Royal Anthropological Institute, at 8.30.—C. W. M. Hart: Grave Posts of Melville Island.

Royal Photographic Society.—Dr. D. A. Spencer: Modern Developments in Colour Photography.

WEDNESDAY, November 11.

Royal Society of Medicine (Surgery: Sub-Section of Proctology), at 5.—W. S. Perrin: Some Landmarks in the History of Rectal Surgery (Presidential Address).

Institution of Engineering Inspection (at Royal Society of Arts), at 5.30.—Dr. G. H. Gulliver: Mechanical Testing of Materials.

Institution of Electrical Engineers (Hampshire Sub-Centre) (at University College, Southampton), at 7.30.—R. M. Charley: Recent Progress in Large Transformers.

THURSDAY, November 12.

Royal Society, at 4.30.—*Papers to be probably read*:—Prof. A. Fowler and Dr. J. S. Badami: Spectrum of the Hydrogen–Nitrous Oxide Flame.—S. H. Bastow and F. P. Bowden: On the Contact of Smooth Surfaces.—W. B. Mann and B. G. Dickins: The Thermal Conductivities of Saturated Hydrocarbons in the Gaseous State.—*Papers to be read in title only*:—L. C. Bailey: The Thermal Conductivities of Certain Approximately Pure Metals and Alloys at High Temperatures.—W. A. Macky: Some Investigations on the Deformation and Breaking of Water Drops in Strong Electric Fields.—M. L. Smith and B. Topley: The Experimental Study of the Rate of Dissociation of Salt Hydrates.

London Mathematical Society (at Royal Astronomical Society), at 5.—Prof. S. Chapman: Tides in the Atmosphere (Presidential Address).

Child-Study Society (at Royal Sanitary Institute), at 6.—Miss Thyra Smith: The Psychology of the Junior School Child.

Institute of Metals (Birmingham Local Section) (at Chamber of Commerce, Birmingham), at 7.—W. A. Benton and others: Discussion on Mechanical Testing.

Society of Chemical Industry (Nottingham Section) (at University College, Nottingham), at 7.30.—Lord Trent: Chairman's Address

Institution of Electrical Engineers (Dundee Sub-Centre) (at University College, Dundee), at 7.30.—J. E. Luckhurst: The Receiving Station at Cupar for Transatlantic Telephony.

North-East Coast Institution of Engineers and Shipbuilders (Tees-Side Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—S. Burns: Electric Grid Change-over.

Oil and Colour Chemists' Association (London Section) (at 30 Russell Square, W.C.1), at 7.30.—R. G. Daniels: Paint Industry in the Future.

Optical Society (at Imperial College of Science and Technology), at 7.30.

Institute of Metals (London Local Section) (at Royal School of Mines), at 8.—Dr. W. J. P. Rohn: Some Recent Advances in Rolling Plant.

FRIDAY, November 13.

Biochemical Society (at Imperial College of Science and Technology), at 3.—T. Moore: High Potency Vitamin A Concentrates.—S. H. Piper: X-Ray Analysis of Certain Long Chain Paraffins, Ketones, and Alcohols.—A. C. Chibnall: The Metabolism of Plant Waxes.—G. H. Bell and A. R. Craig Paterson: A Chart for *p*H Calculations.—J. A. B. Smith: The Glyceride Fatty Acids of Certain Forage Grasses.—C. R. Harington and S. S. Randall: Synthesis and Properties of *i*-*β*-Hydroxyglutamic Acid.—W. L. Davies: The Inactivation of Lipase in Dairy Products by Traces of Heavy Metal Salts.—J. Pryde and R. T. Williams: The Structure of Borneol Glucuronic Acid Synthesised *in vivo*.—T. S. G. Jones and E. T. Waters: A Note on the Sugar of the Nucleic Acid of *Bacillus Tuberculosis*.—H. J. Phelps: The Influence of Hydrogen-ion Concentration on the Response of Tissues to Histamine.—P. V. McKie: The Nitrogen Metabolism of the Lupin Seedling.—A. C. Chibnall and R. G. Westall: The Estimation of Glutamine in the Presence of Asparagine.—J. M. Gulland and W. H. Newton: Observations on the Purification of the Oxytocic Principle of the Posterior Lobe of the Pituitary Gland.—*Demonstrations*:—S. H. Piper and A. C. Chibnall: Apparatus for Distillation in High Vacuo of Substances with a High Melting Point.—G. H. Bell and A. R. Craig Paterson: A Chart for *p*H Calculations.

Royal Society of Arts (Indian Meeting), at 4.30.—Lt.-Col. M. L. Ferrar: The New Penal System in the Andamans.

Malacological Society of London (at Linnean Society), at 6.

North-East Coast Institution of Engineers and Shipbuilders (at Mining Institute, Newcastle-upon-Tyne), at 6.—J. W. Hobson: The Care and Maintenance of the Industrial Steam Locomotive.

Institution of Electrical Engineers (London Students' Section), at 6.15.—W. A. Bishop: Short Wave Transmission.

Institution of Welding Engineers (at Chamber of Commerce, Birmingham), at 7.—E. W. Thompson and A. Jeavons: Some Details of the Progress reached in Forge and other Welding in Boiler Works Practice.

Junior Institution of Engineers, at 7.30.—Annual General Meeting.

Institute of Metals (Sheffield Local Section) (at University, Sheffield), at 7.30.—E. A. Smith: Engineering Silver Solders

Society of Chemical Industry (Chemical Engineering Group) (at Chemical Society), at 8.—D. McDonald: Platinum.

SATURDAY, November 14.

Royal Institution of Great Britain, at 3.—F. E. Yerbury: Present-Day Architecture on the Continent: Modern Buildings in Scandinavia.

PUBLIC LECTURES.

SATURDAY, November 7.

Mathematical Association (London Branch) (at Bedford College for Women), at 3.—A. W. Siddons: The First Two Years of Geometry in a Secondary or Preparatory School.

Horniman Museum (Forest Hill), at 3.30.—D. Martin Roberts: London in the Age of Dr. Johnson.

TUESDAY, November 10.

University College Hospital Medical School, at 5.15.—Dr. Harriette Chick: Vitamins and Disease. (Succeeding Lecture on Nov. 17.)

WEDNESDAY, November 11.

Royal Institute of Public Health, at 4.—Prof. Winifred Cullis: The Health of the Woman Citizen.

THURSDAY, November 12.

Science Museum, South Kensington (in connexion with Exhibition of Modern Glasses), at 4.45.—R. F. Taylor: Sheet and Plate Glass.

FRIDAY, November 13.

King's College, London, at 5.30.—J. Benda: L'exploitation de la Science par la Littérature au 19e Siècle.

Bedson Club (at Armstrong College, Newcastle-upon-Tyne), at 6.30.—Prof. J. Read: Some Researches on Essential Oils.

Chadwick Trust Lecture (at Gateshead).—Sir Robert Philip: The Outlook on Tuberculosis—Now and Then

SATURDAY, November 14.

Horniman Museum (Forest Hill), at 3.30.—M. A. Phillips: Nature at Home.

DISCUSSION.

Thursday, November 12.

Faraday Society (at Chemical Society), at 8.—Discussion on the following papers by Dr. E. W. J. Mardles:—

- (*a*) The Oxidation in Air of (*a*) Carbon Disulphide, and (*b*) Carbon Monoxide.
- (*b*) The Oxidation of (*a*) Hydrogen, (*b*) Methane, and (*c*) Coal Gas in Air.
- (*c*) Comparative Study of the Vapour Phase Oxidation in Air of (*a*) Ethane and Ethylene, (*b*) Pentanes and Amylenes, (*c*) Ethyl Alcohol and Amyl Alcohol, (*d*) Acetaldehyde and Valeraldehyde.
- (*d*) The Oxidation of Fuel Vapours in Air: Experiments with (*a*) Aromatic Hydrocarbons, (*b*) Cyclohexane, and (*c*) Cyclohexene.
- (*e*) The Oxidation of Acetylene in Air.

CONGRESS.

November 7 to 11.

Allgemeine Mitgliederversammlung der Aeroarctic (at Berlin).

Saturday, Nov. 7.—Prof. Weickmann: Die Wetterlage vor und während der Forschungsfahrt des "Graf Zeppelin" und ihr Einfluss auf den Kurs der Expedition.

Prof R. Samoilowitsch: Die geographischen Beobachtungsergebnisse.

Dr. Ljungdahl: Die erdmagnetische Ausrustung und die Beobachtungsergebnisse.

Lt. Comdr. Smith u. Dr. Kohl-Larsen: Über die Eisbeobachtungen.

Prof. Moltschanoff und Prof. Weickmann: Die aerologischen Instrumente und Beobachtungsergebnisse.

Sunday, Nov. 8.—Prof. v. Gruber und Dr. Aschenbrenner: Über die photogrammetrische Ausrustung, die Arbeits- und die Auswertungsmethoden des auf der Expedition gewonnenen photogrammetischen Beobachtungsmaterials.

National Needs.

> "*The great trouble is that the civilisation of to-day is still of a very low degree. We talk big and think small. Only a few of us even know how to read . . . we need a long initiation in almost any subject before our reading about it is likely to be of any value.*"—ELLWOOD HENDRICK: "Percolator Papers".

THE present sore trouble of the world, which has long been surely coming upon us owing to the inconsidered action of all nations, will not be without its compensations, if we be led to probe into the causes and to reorganise our operations upon considered lines.

The call is upon us all to turn our attention to affairs of State. Scientific workers especially have to recognise that they have been selfish in their too exclusive devotion to experimental study and the immediate development of their discoveries; that they have soared entirely above the heads of the community and in no way prepared the masses to understand the profound changes brought about in our life by the scientific forces at work in industry. Brains and brawn were never so far apart as now. Although this is the case, it was never so clear that a wise socialism is foreshadowed as the only possible way of avoiding the downfall of our civilisation. In some way or other, the nations must come to work together. Competitive industry, as we have known it in the past, is ceasing to be possible: it pays no one and is but a disguised civil war. Mechanisation is bringing about its own defeat: the cost of displacing human labour is becoming prohibitive. Man is ever there; capital will not long be, at present rates of taxation: we shall soon be forced to return to *manu*factures.

The chief duty before us clearly is—to make all men work: a machine which is idle has no right to be. Nature herself ever works and necessarily dies if she cannot. Man alone of her works is ceasing to be natural and fast becoming a mere parasite.

The country is now in the hands of a Government elected upon a National ticket; the popular expectation is, that it will be Rational and rise superior to party. There is, however, an ominous preponderance of men of rigid outlook bearing political labels; few are known to profess a belief in government by scientific methods. Probably the Prime Minister alone can attach any real meaning to the term 'scientific'. He was long an attendant at Royal Institution lectures and grew up in a scientific atmosphere. Very remarkable, at the recent Faraday celebration in Queen's Hall, was the entirely sympathetic way in which he entered into the spirit of the occasion, outshining all other speakers in clearness of perception of the service rendered to the world by Faraday, especially the moral value of the example set by this great experimentalist. His father-in-law, we know, was the most sympathetic of Faraday's biographers. Probably Sir John Simon comes next to Mr. MacDonald. He at least has breadth of outlook and a severely logical mind.

It is much to be feared that the men who have taken upon themselves to govern us cannot possibly fathom the depth of present-day world activities: the overwhelming complexity of the issues; the subtle problems they present; the hopeless difficulty of meeting the naturally selfish dictates of human nature. Earl Grey being all but out of action, there is no prophet in the field of politics. We need a Disraeli, a man of imagination, able to grasp our modern problems and be a constructive leader. If the recent election have shown one thing more than another, it is that the country is prepared to follow a clear lead. In this particular, Mr. MacDonald and his small band of devoted followers have set a noble example.

Nothing could be more definitely painted upon the wall than the failure of our public schools to train the ruling classes in any proper way. The 'science' introduced into them has been to no purpose—no effective teaching has been given in the logic of method. Consequently, the calculated practice of scientific argument—the habit of sound scientific thought—plays no part in our affairs; it has no considered place in our Civil Service. This is one of the matters of urgency, calling for fullest consideration, at the present moment. Unless and until our universities and schools are brought into harmony with the times, no real progress can well be made. Oxford most needs reformation: the present neglect of a broad culture by the University is a national danger. As to the schools, it should be deemed a criminal act to bring up a boy or girl upon literary study alone, without training in the judicial method.

Our schools still teach little more than the worship of words and those largely words of the past. The men in charge of them, with few exceptions, have no feeling for the wide issues of practice and scientific leadership. We are a strange people: intensely practical in our general outlook, we place ourselves in the hands of those who cannot possibly become masters of the intricate situation which confronts us. Teachers as a class in no way grasp the responsibilities of their position, let alone the dangers of the times. They are too much of one school and, with rare exceptions, of an unadventurous type. Complaint of the inflexible nature of the material they produce is rampant everywhere.

Lafcadio Hearn, writing from Japan, in August 1893, in an outspoken letter to Ellwood Hendrick, after remarking how terribly tragic modern life is becoming, directs attention to its hopeless contradictions. These, he says,

> "can only be recognised and reconciled through a profound knowledge of social conditions, not in the abstract only but in the most complex operations. This is the theoretical recognition. The practical recognition requires special hereditary gifts—intuitions—instincts—powers. Mere education in business alone won't do. That only makes servants. Masters must be natural masters of men. Life is an intellectual battle but not a battle to be fought out by mere chess-combinations. It is also a battle of characters. . . . I do not see much likelihood of moral development . . . morals have been at a standstill since the beginning of history: we have made no apparent progress in that. Then comes the question, Are we not developing immorally?"

There can be little doubt as to the answer. The Hollywood atmosphere in which the masses now live—the scorching, motor habit, developed as a mere means of escaping from the boredom of mental vacuity—the condition of the Press, which for the most part has no soul beyond sexuality and sport: all these things are proof sufficient that there is no real intellectual progress to be recorded. The masses have learnt to read—but "the hungry sheep look up and are not fed". The body scientific—those who hold the keys of knowledge—makes no calculated effort to provide them with food. The literary class, as a body, has no message; brought up upon words alone, with myopic uncultivated vision, it can only use words to describe the obvious.

Not so long ago, starting from Huxley and Herbert Spencer, a body of men representative of natural science, in its various branches, made a determined effort to galvanise the schools into practical scientific activity and make education an introduction to life: the attempt has been a failure. Scarce any of the band remain. Modern scientific workers—the professional researchers—no longer take interest in such matters. Occasionally someone kicks: Prof. Irvine Masson is the latest example. The bookmen hold the field: what public conscience there may be is stilled by free education and scholarship grants. We have little right to complain of politicians, so long as we make no effort to train them to their office by bringing about the revolution which every thinking man knows to be long overdue in our school system.

Meanwhile the industrial shoe pinches terribly. There isn't enough leather to make it a comfortable fit. We are so pampered into the belief that we can live on industrialism, that no real thought is given to the problem as a whole. The fetish of what is supposed to be cheapness is worshipped without any consideration of its consequences. No sense of the meaning and value of agriculture has been bred into the community.

The mathematicians can discuss the Unseen Universe with great popular effect. Yet they make no attempt to stem the ignorance of the money-changers or help them to devise a rational system of banking which will enable us to do without the gold we cannot have, wherewith to back the counters issued as money—so that commerce may be controlled and its operations made facile, not the sport of speculators. The multitude obviously does not understand the meaning of the term *standard*: the professed economists have not the wide equipment that is needed for their task.

Men now need to be so trained that they learn to work together—without losing their souls. No trade to-day is free; some combine is at work which prevents each one from being fair. So long ago as 1894, Hearn could write to Hendrick prophetically:

> "The tyranny of the future must be that of Organization: the monopoly, the trust, the combination, the associated company . . . much more powerful than the robber-baron . . . these are infinitely less human—having no souls."

Hearn spoke as an artist, of course. Still, his plaint is justified in a tyranny such as is being exercised over milk production, by the great combines now coming into action as universal purveyors. Water has long since passed into public control: milk someday perhaps will be seen to be of even greater consequence and cared for properly.

We have no food sense worth calling a sense: biology to this end is not taught in the schools; women decline to cook and are deluding themselves into a belief in canned foods. Our ignorance of all essential things is monstrous. Scared by a few bacteria, we systematically spoil our milk. We are even threatened with synthetic food. Machinery, using the sunshine of past ages, is to put the nose of our present sun out of joint and make the farmer a back number. Our only salvation is the natural horse sense that is in us. Meanwhile, proof is being quietly accumulated that if we but choose to cultivate our land with considered care and knowledge, we can make not two but many blades of grass to grow where one is now starved—and largely feed ourselves, with food of a quality unprocurable from elsewhere. These are the things to be considered in framing our national, rational policy. Fair trade in food should be the first demand satisfied, however tentatively we may proceed. To this end, we need to develop a great scientific organisation. The farmer's chief protection should be—our determination to help ourselves!

In future, the scientific worker, to be worthy of the name, must justify himself through social service in the first instance. Our situation is so grave that he must be militant without delay and in every quarter. H. E. A.

A Doctrine of University Functions.

Universities: American, English, German. By Abraham Flexner. Pp. ix+381. (New York, London and Toronto: Oxford University Press, 1930.) 16*s*. net.

THIS volume is an expansion of three lectures, given at Oxford in 1928, which excited a considerable amount of journalistic comment by reason of the author's severe animadversions upon the University of London. Apart from sensational attractions of that kind, any study of the functions and organisations of universities written by so well-informed and acute an inquirer as Dr. Flexner is bound to be worth careful attention; and a dispassionate reader of the present book must admit that it is a weighty and timely work, in which the author has set down, with the utmost directness and clarity, criticisms and positive views that demand the anxious consideration of all who are concerned with university policy.

In the courageous performance of his task, Dr. Flexner has felt obliged to dwell long and to fall heavily upon the errors and follies of certain universities. No one could accuse him here of patriotic partiality; for if he has chastised the University of London with whips, he has chastised some of the greatest of American universities with scorpions. Indeed, the reviewer felt that it was indecent for him, a foreigner, to be present at the merciless castigation of these famous institutions; and, in his embarrassment, turned over quickly the more deeply ensanguined leaves. Doubtless it is salutary for an institution to have its sins shown up without fear or favour, but in doing the thing so thoroughly Dr. Flexner has incurred certain risks. Human nature being what it is, there is the possibility that the institutions which might have profited most from his admonitions will harden their hearts against him and seek to defend their ways; it is also possible that the great achievements of the universities which fall most under the author's scourge may be forgotten, notwithstanding his generous praise; and above all, there is the danger that the reader's attention may be distracted from the main purpose of the book—which is to develop a positive doctrine of university functions and to use criticism of activities which the author regards as misguided simply to throw into clear relief those which he deems to constitute the proper work of a modern university.

Dr. Flexner's idea of a university (he borrows the phrase, of course, from Cardinal Newman) is expounded in the first chapter. Universities, being highly representative organs of national consciousness, must differ, sometimes in important features, in different countries; but in the ideal university "we should see to it that in appropriate ways scholars and scientists would be conscious of four major concerns: the conservation of knowledge and ideas; the interpretation of knowledge and ideas; the search for truth; the training of students who will practise and 'carry on'" (p. 6). Here, in brief, is the theory which, expanded in an illuminating manner in subsequent pages and from time to time throughout the book, is the basis of his criticism of what is, and of his hopes with regard to what may be. In the author's view—constantly reiterated—universities should resolutely concentrate upon the 'concerns' he has laid down for them, leaving other educational functions, however important they may be, to be carried out elsewhere.

This does not mean that universities are to be cloistered institutions, remote from the world and its practical problems. On the contrary, a main charge in Dr. Flexner's indictment of existing universities is that they fail to recognise fully their obligation to give intellectual guidance to the community; that they suffer too wide a 'social lag' to exist between their interests and activities and the urgent problems of the day; and that they confine their study of those problems within far too narrow a field. His point is that while a university should care greatly about the important problems that arise in the practice of any of the major professions, such as engineering, medicine, or teaching, or in the practice of government, or in the sphere of economic relations, its attitude towards them must be strictly theoretical: that is, it must seek to solve the problems but has no concern with exploiting the solutions. Having solved one problem, the university research worker must pass on to another, leaving developments and practical applications to those concerned with them.

One can scarcely fail to recognise the nobility of Dr. Flexner's concept of universities as places where thought and disinterested inquiry are pursued upon the highest levels, and where the best minds of each generation are trained for intellectual achievement. It is perhaps realised most closely at the moment in the Hebrew University of Jerusalem, an institution finely directed and inspired, and as yet uncorrupted by age or prosperity. Among the universities which Dr. Flexner reviews, none rises so near to his ideal as this shining example; but Oxford and Cambridge and the German universities come nearest. It is a relief to an Englishman's fears to find our ancient universities placed so high, and it is also interesting in view of the serious discrepancy between their practices and the author's canons of university behaviour.

Judged by those canons, Oxford and Cambridge give far too much attention to what is in effect secondary education, and have been misled (Jowett's work at Balliol is the capital instance) by the notion that training for service is a proper function of a university. Nevertheless, there is in them something, a little difficult to explain, which makes them great institutions of learning. They have their honours schools, and they permit—though it can scarcely be said that they help—men of outstanding force to become centres of really advanced work and thought. Above all, their traditions make it impossible for them to degrade their dignity and to waste their spiritual resources by pandering to the demands which have drawn American universities so far from the true path. There remains, however, very much to be done if they are to play the part that modern universities should play in the affairs of a great nation and in the interests of civilisation as a whole; and many pages are given by Dr. Flexner to the detailed exposition of his ideas as to the directions which the required developments should take.

Dr. Flexner cannot understand in what sense the University of London is a university at all. The institutions which it comprises are too heterogeneous in quality and purpose, and the control exercised by the central machinery over policies is too limited and indirect to secure the unity essential to a real university. Moreover, he finds much to criticise in the constitutions and powers of the two highest organs, the Court and the Senate. Incidentally, in stating (p. 237) that the Court "contains no professors", the author makes an error which could so easily have been avoided that one is led to wonder whether his statements of fact elsewhere may not be vitiated by mistakes which tend, as in this instance, to give improper support to important inferences. It may be further noted, in this connexion, that Dr. Flexner does not mention that the statutes ensure in the Court a clear majority of persons who are also members of the Senate—a provision which makes very remote some of the evil possibilities he foresees.

The greatest weaknesses of the University of London as Dr. Flexner sees it are, first, that, regarded as the body governing its constituent institutions, it is almost entirely external to them all, and next, that some of the constituent institutions and much of the work done in most of them have no proper place in a university. To some extent the provincial universities fail in the same way; but their unity saves them, and, on the whole, they represent—as do the American State universities—" an amazing achievement within a brief period ".

It is not possible to summarise here Dr. Flexner's interesting and sympathetic account of the German universities. It is well known that there are several respects in which their position and methods contrast almost violently with those of the English universities. Most conspicuous is their dependence upon the State and the way in which, notwithstanding that dependence and the evils it has recently brought about, they have, on the whole, conserved their *Lehrfreiheit* and *Lernfreiheit*. Equally characteristic and different from English practice is the responsibility they cast upon the student, who " is treated as a man from the day he matriculates ".

It would also take too long to consider Dr. Flexner's treatment of important specific problems of university work and organisation—such as the organisation of medical research and training, upon which he writes with admitted authority. On the other hand, the reviewer cannot resist making an attempt to set down some of the doubts with regard to Dr. Flexner's theory of universities which his admiration of the author's largeness and loftiness of view has not prevented from rising.

One of the greatest of American teachers once voiced a distrust of all " rational, clear-cut, temple-like " systems of thought. William James's epithets together with the feeling they expressed come into one's mind in contemplating Dr. Flexner's conception of the educational institutions of a country with the universities, Olympian in their elevation and their detachment, at the top. One questions whether the universities can perform with full efficiency the high, abstract functions he rightly allocates to them, if their activities are restricted to those functions with the rigour which he would enforce. Granted that a university may (for the sake of the fees) give too much attention to ' secondary ' teaching, and may be tempted (for the same reason or better ones) to interpret too widely its duty in the matter of ' service ', is it not true, nevertheless, that some contact with these things, in their higher, more definitely intellectual forms, is necessary to preserve in the loftier regions of the institution a proper balance and sense of reality ?

The argument is put here from the point of view of the university. From the point of view of professional or ' service ' institutions, it seems obvious that direct contact with the spirit of exact inquiry which lives in a university, and with the atmosphere of intellectual adventure which should prevail in it, is the best if not, indeed, the only means of maintaining a high level of professional teaching and study. Dr. Flexner's opinions here (we respectfully suggest) are influenced by a view of the " training of the mind " which any psychologist (if he believed in psychologists) would assure him is sadly out of date. This is illustrated by his story of the professor's wife whose " powers trained elsewhere " enabled her to produce " an excellent loaf ", and of the " astonished Bridget's " comment : " That's what education means—to be able to do what you've never done before ". In brief, Dr. Flexner's censure of the ' service ' activities of universities—where they are not plainly justified by the low intellectual level of the institutions condemned—is based upon an uncritical acceptance and a far too sweeping application of Bridget's theory of education.

Lastly, it seems possible that the same tendency to take an abstract and too simplified view has prevented Dr. Flexner from doing justice to the University of London. One would gather from his pages that the good work done in the more important institutions is done in spite of the constitution rather than with its aid ; yet that is by no means the view held, as a rule, in the institutions themselves. For example, Prof. Hearnshaw's centenary history of King's College shows how that institution was rejuvenated—one might almost say recreated—by entering into the new teaching university; and Sir William Beveridge recently gave impressive evidence of how the peculiar combination of autonomy with central control, which Dr. Flexner finds so illogical, serves to foster the individuality of the colleges, while tending to maintain common standards of efficiency—to say nothing of a common university consciousness—in all. But to offer these critical remarks is not to deny the outstanding importance of a book the value of which will become more clear the more thoroughly it is studied.

Laboratory Technique in Physical Chemistry.

Ostwald-Luther Hand- und Hilfsbuch zur Ausführung physiko-chemischer Messungen. Unter Mitwirkung von W. Bothe, W. Gerlach, R. Gross, H. v. Halban, R. Luther, F. Paneth, F. Weigert. Herausgegeben von C. Drucker. Fünfte, neubearbeitete Auflage. Pp. xix + 979. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1930.) 52 gold marks.

"OSTWALD-LUTHER", the preface to the first edition of which is dated 1893, is a work which is known in every laboratory of physical chemistry in the world. It has, in its successive editions, proved a reliable guide to experimenters, and many of the methods which, in the early editions, were perhaps not very well known even in physical chemical laboratories specialising in this type of work, are now commonplaces in technical laboratories. The book has never professed to give a course of experiments suitable for the use of students, but seeks to explain the principles of methods which are used, or are likely to be used, in research work, and the great progress which has been made in the development of such methods has called for a considerable extension in the scope of the book.

It is clear that, even in a book of nearly a thousand clearly printed pages, it is impossible to enter into detail regarding all the experimental technique which the modern physical chemist must have at his disposal. What may reasonably be expected is that the book shall deal with the broad fundamental parts of the subject in some detail, and that it shall provide indications where fuller information on special points can be found. In the last respect, it may reasonably be anticipated that in a book of this size and price an international outlook shall be maintained, and it must be said at once that, in spite of the obvious distaste towards a criticism of a previous edition that it fell short in this respect, a distaste expressed in the preface, much more could usefully have been done in taking account of the contributions of British and American workers. There would be no useful purpose served in entering into detail on this point, but in many parts of the book there is no mention of important work which should have found a place. In some cases this work is merely mentioned by references to German abstracts, a practice which has nothing to recommend it, since the English-speaking chemists have long possessed reliable abstracts in their own language, and will not welcome a journey to a large public library in order to turn up, in a collection of German abstracts, the reference to a paper which is on their own shelves in the original. It is essential that the authors of such a work as this shall not only have read the paper in the original, but that they shall also provide their readers with a reference to the latter.

It is clearly impossible within the limits of space imposed on a reviewer to enter into a detailed discussion of the whole of such a comprehensive work. What has been done, therefore, has been to select a few representative sections at random, and to see how far these cover the more recent work which they profess to describe.

The section on transport numbers gives a fairly comprehensive account of the Hittorf method, with a useful example of calculation, but it is much too brief in connexion with the direct method. Although references are given to some papers by McInnes, no attempt is made to describe in any way the apparatus used. It may be said that space did not allow of this. If this is so, it may be suggested that the by no means negligible space used in giving the names and addresses of German firms supplying squared paper, slide rules, logarithm tables, glass, etc., could have been better utilised, since no user of the book will be likely to trouble himself with such matters.

In the section on surface tension, the methods described are somewhat old-fashioned, and the corrections to be used in the capillary tube method are not given. The section on the viscosities of gases is poor, and the rule for the ratio of length to diameter of the tube, given at the top of p. 313 (from a very old paper by Meyer), is misleading, since the real factor is the nature of the flow in the tube, about which nothing is said. No account is given of measurements at high temperatures. The section on the specific heats of gases is also far from satisfactory, and recent collective accounts of the subject are not mentioned. Not even a reference is given to more recent experimental methods used for the determination of the ratio of specific heats, or to measurements by the explosion method, except those of German authors. The whole section on this subject occupies only about two pages. In the section on dielectric constants there are only five references, all to German authors, the whole of the recent American work being unmentioned. Spectrometry in the infra-red is represented by three lines of type, no reference being made to recent important English work.

It is possible that the sections chosen for notice were unfortunate. To them, at least, the criticism to which the authors take exception applies completely. English and American readers will not feel satisfied, after the purchase of large and expensive German books, if information which they might reasonably expect to find in them is missing.

Although the present edition of "Ostwald-Luther" is far from being up to date in some sections, and is overburdened with too much irrelevant matter, the classical parts of the work, if they may be so called, remain, and those who have no edition of the book in their possession will find it of the greatest value in the physical chemistry laboratory. The information on the more recent advances will also serve a useful purpose, provided that the reader remembers that there is much good work, some even fundamental, to which no reference whatever is made. The printing and paper are of the best quality. J. R. P.

Physiological Perception of Position.

The Physiology of the Vestibular Apparatus. By Mario Camis. Translated and annotated by R. S. Creed. Pp. xiv + 310 + 27 plates. (Oxford: Clarendon Press; London; Oxford University Press, 1930.) 21*s.* net.

PROF. CAMIS deserves the thanks of all physiologists for bringing together into one book the mass of knowledge—very largely of modern growth—concerning the vestibular apparatus of animals. The gap thus filled, and the extent of his service, is amply shown by the long and complete bibliography given in the book—where, save for de Cyon's polemical book of 1908, the last treatise devoted *entirely* to this field is Ewald's "Nervus Octavus", which appeared so long ago as 1892.

The author commences with an interesting account of Marey's cinematographic demonstration in 1894 of the righting movement by which a falling cat drops upon its paws—a demonstration not only of interest because of the dynamical problem it set, but also as one of the first results of the cinematographic method developed, and largely originated, by Marey himself. The dynamical problem is discussed and solved, and the subject of the dropping cat—which at one time or another has fascinated most young people, and Clerk Maxwell amongst them, if we are not mistaken—is then itself dropped, to give place to an account of the older work on the physiology of the labyrinth. This brief historical survey deals chiefly with the theoretical conclusions of Flourens; of Goltz; of Crum Brown, Breuer, and Mach; of de Cyon; and finally of Ewald. Next follow chapters on the anatomy of the vestibular apparatus and of its central nervous connexions, and on the operative methods used in experiments.

A chapter upon the effects of experimental lesions of the labyrinth is followed by a complemental one upon the effects of stimulation, and that by an interesting and valuable discussion upon the labyrinth as the organ of the sense of space. The theories and speculations of de Cyon are ably summarised here in their bearing on the philosophical teaching of Kant; and there follows an account of other views with regard to the functions of the labyrinth. This closes the story of the older work and views on the function of the labyrinth. The remaining half of the volume under review deals with the modern investigations and conclusions.

Modern investigation has been directed, chiefly by Magnus and his pupils, to the function of the vestibular apparatus and its connexions in the *reflex* activities of the animal; and Prof. Camis prefaces his description of this work with a brief account of Sherrington's development of the reflex theory. This is followed by an excellent summary of the work on non-labyrinthine postural and righting reflexes; and that by a description of the labyrinthine reflexes and their influence on the tone of limb muscles. A following chapter is given to the description of the relations of the labyrinth to the eyes; then comes an analysis of labyrinthine reflexes, and an interesting appendix on the terminology and classification of reflexes. Later chapters are devoted to the adequate stimulus for the receptive end-organs of the labyrinth, and to the nervous connexions of the vestibular apparatus.

Prof. Camis presents this complex subject in a most clear and readable manner. Our debt to him is great; but we have another debt to acknowledge. Not only is Dr. Creed's translation so good that we forget that the original was written in Italian, but he has also added many notes which increase the value of the book.

Short Reviews.

Brain, Mind and the External Signs of Intelligence. By Dr. Bernard Hollander. Pp. 288. (London: George Allen and Unwin, Ltd., 1931.) 12*s.* 6*d.* net.

THE book opens with an introduction in four parts: the nature of the mind, the ascent from unconsciousness to self-consciousness, the development of the human mind, and the development of the human brain. Into these twenty-five pages is compressed a great deal of important matter lucidly treated.

Chapter ii. is devoted to a critical account of the results of the experimental physiology of the cortex cerebri. To follow this admirable historical résumé, a considerable amount of previous knowledge of cerebral physiology is needed, so that the layman may be somewhat puzzled by the contradictory accounts of the results of experiments upon the cerebral cortex. The omission of the name of Gall from this discussion is curious, since Gall undoubtedly held views far in advance of those of his contemporaries. Indeed, for locating ' moral sentiments ' in ' mere matter ', he was expelled from Vienna

Dr. Hollander, of course, believes in the localisation of cerebral function, and in particular inveighs against the notion that the brain ' acts as a whole ' —a vague statement to which no qualified neurologist would to-day subscribe. The work of Head and Gordon Holmes on the localisation of ' emotive reaction ' in the thalamus is duly referred to, and the James-Lange theory of the peripheral origin of emotion is promptly dismissed. The chapter on the histology of the cerebral neurons is excellent, though here again the unfortunate lay reader—for we presume Dr. Hollander writes also for him—must crave for an illustration or two, to render visible to him such things as ' arborisations ', ' axons ', and ' dendrites '. It is curious not to find ' synapsis ' in the index.

It should, however, be said that the diagrams, illustrations, and portraits provided are excellent; indeed, the book is quite valuable for these alone.

The author gives expression to a number of much-needed cautions on the subject of the correlation of intellect and size or weight of the brain. A large portion of the work is occupied with a detailed study of the functional importance of the human frontal lobes, and here, as elsewhere, there are full references to original sources in clinical and other literature. D. F. F.-H.

Gmelins Handbuch der anorganischen Chemie. Achte vollig neu bearbeitete Auflage. Herausgegeben von der Deutschen Chemischen Gesellschaft. Bearbeitet von R. J. Meyer. System-Nummer 26: *Beryllium.* Pp. viii+180. 30 gold marks. System-Nummer 58: *Kobalt.* Teil B: *Die Ammine des Kobalts.* Pp. xxv + 376. 58 gold marks. (Berlin: Verlag Chemie G.m.b.H., 1930.)

THE new volume on beryllium will be welcomed on account of the interest which is being taken in the commercial production of the metal and of its alloys, known to have valuable properties. The literature has been reviewed up to May 1930 and the result is a very useful compendium of information. It must, of course, be borne in mind that this is a work of reference, in which results are recorded so far as possible in chronological order, rather than a textbook to guide the reader in his choice. Thus, many methods are described of obtaining beryllium from its chief ore, including the separation of the metal from aluminium by means of the different solubilities of their fluorides, although no preference is indicated. Again, there is no hint to show that electrolytic methods of reduction are to be preferred to purely chemical methods. While the volume contains a list of references to researches on the alloys of beryllium, the detailed account of the alloys must be sought in other volumes of the work.

The immense group of the cobalt ammines has grown not only in extent but also in importance since the well-known researches of A. Werner gave the clue to modern developments of the theory of molecular structure and of valency. Thus, a separate volume is now devoted to this subject, which includes between two and three thousand derivatives, practically all of which fall into the scheme of classification, which is carefully explained in the opening chapter. This is followed by the systematic treatment of the ammines of bivalent and of tervalent cobalt, the latter occupying the greater part of the volume. The literature is reviewed to the end of 1929.

Geologie der Steinkohlenlager. Von A. Dannenberg. Band 2, Teil 2. Pp. 125-270. (Berlin: Gebrüder Borntraeger, 1930.) 14 gold marks.

THE part of this work under notice deals with some of the coalfields in eastern North America. Among those in the United States it describes the fields of West Virginia and those of the Appalachians—both the northern basins in Kentucky and Tennessee around the famous Cumberland Gap, and the southern basins in Alabama and Georgia, including the Birmingham fields and the Cahaba and Coosa basins. The part also describes the Michigan coal basins and those of the series grouped as the Western Interior Basin, which ranges from Iowa southward across western Missouri, Kansas, Arkansas, and Oklahoma, and is continued to the south of the Arbuckle Mountains into Texas. A brief reference is given to the coal of Alaska. The rest of the part is devoted to the coalfields of the maritime provinces of Canada and Newfoundland.

In reference to each field, the author describes the succession of the sediments and coal seams and the tectonic structure of the field and gives reference to the literature. The summary of the southern part of the western interior field is of special interest owing to the extensive recent literature upon it.

Chemische Bindung als elektrostatische Erscheinung. Von A. E. van Arkel und J. H. de Boer. Deutsche, von den Verfassern autorisierte Ausgabe von Li Klemm und Wilhelm Klemm. Pp. xx+320. (Leipzig: S. Hirzel, 1931.) 15 gold marks.

THIS monograph deals with the study of compounds from the point of view of Kossel's theory and the method of calculation of Born, in which Coulomb forces and a force of repulsion varying inversely as a higher power of the distance are assumed. It carries the theory as far as is possible in this direction and gives a useful and suggestive picture of many important properties of compounds which are amenable to this treatment. The applications of the newer quantum theory, including wave mechanics, find only a subordinate place, and the theory of covalent compounds is necessarily very restricted. Within the limits imposed by the method of treatment, the book provides a useful summary of recent investigations and also includes many numerical results of value.

The Jungfraujoch Scientific Station.

PHYSICISTS and meteorologists who are interested in the upper atmosphere, and biologists who wish to study the effects of different altitudes on living organisms, have hitherto been severely handicapped in Europe for lack of adequate facilities for their investigations, yet in spite of this much valuable work has been done in the past. But such places as the observatory on Mont Blanc, the Capanna Margherita on the summit of Monte Rosa, and various Alpine huts which have at different times served as laboratories for scientific work, are difficult of access. Situated as they are amid the higher peaks of the mountains of central Europe, and accessible only after crossing glaciers and snowfields where human transport alone is available, the problem of provisioning and maintaining a scientific expedition and arranging the carriage of its equipment is a very serious one and has imposed a limit on the duration and the scope of the investigations which have been undertaken. Moreover, the available accommodation has been but scanty and protection from storm and frost inadequate, while the risk has to be run that communications may be severed by a change in weather. The outlook has, however, been completely altered by the establishment on the Jungfraujoch of a properly built and well-equipped laboratory, which was formally opened at the beginning of July. The illustrations accompanying the present article are from a *Festschrift* published to commemorate the occasion.

The idea of building such a laboratory is no new one, for it dates back to the days when the Jungfrau railway was first planned. The scheme received the ardent support of the late Prof. A. de Quervain and was fostered by the Swiss Naturforschende Gesellschaft; but lack of funds for long prevented its realisation. Recently, however, the co-operation of Switzerland, Germany, France, Great Britain, Austria, and Belgium, with further financial assistance from the Rockefeller Foundation and from other benefactors and the invaluable aid of the Jungfrau Railway Company, has made possible the foundation of an international research station.

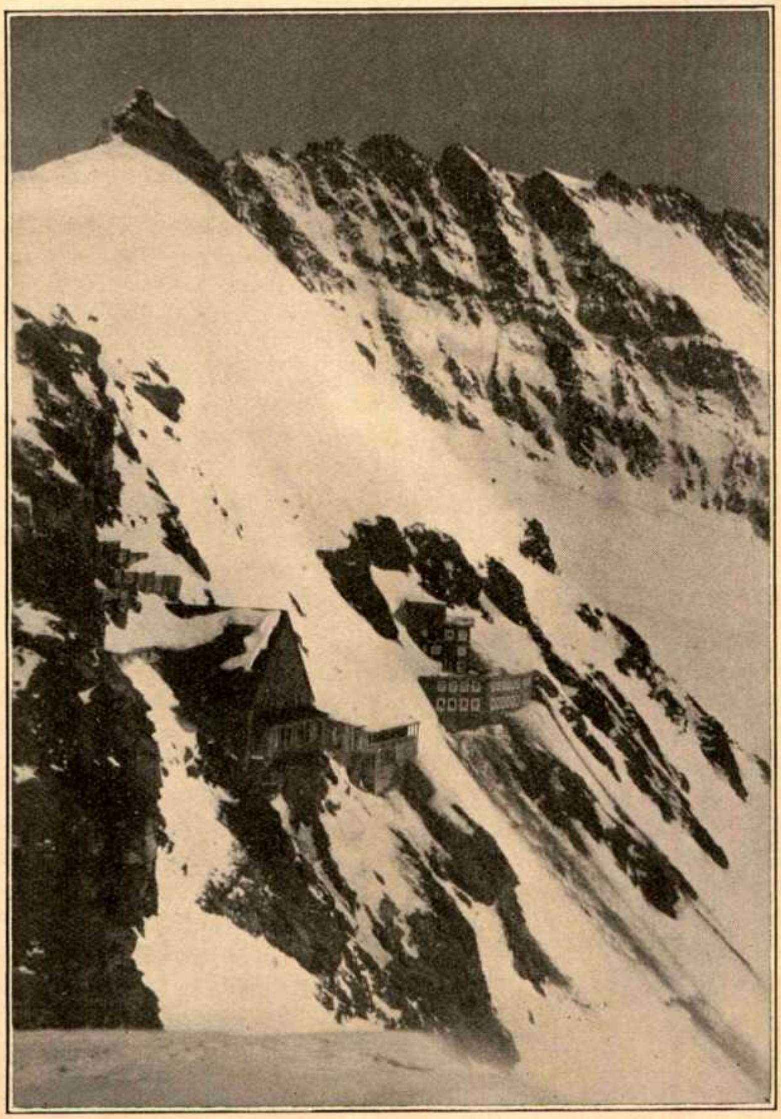

Photo.] [R. Schudel, Grindelwald.

FIG. 1.—General view of the Jungfraujoch Scientific Station.

The Jungfraujoch Scientific Station has been built at an altitude of 3457 metres (11,340 ft.), on a shelf formed by blasting in the rock face which falls steeply towards the snowfields from which the Great Aletsch glacier takes its origin. The laboratory faces south, with the panorama of the Bernese Oberland before it, and a short ascent to the summit of the Jungfraujoch gives an uninterrupted view towards the north. Its general position is shown in Fig. 1.

The building in the foreground is the Hotel Berghaus at the terminus of the railway: beyond this is the new scientific station, access to which is gained through a tunnel in the rock connected with the railway station. Fig. 2 shows a closer view of the laboratory and gives a good idea of its construction.

The laboratory is substantially built of stone to the designs of Messrs. Pfister, of Zurich, and the roof is specially strengthened to withstand falls of stone or snow from the mountain slope above. The walls are cork-lined to ensure warmth, and the living-room and bedrooms are, in addition, panelled with wood. The main block is of two stories, and is surmounted at one end by a tower of three additional stories.

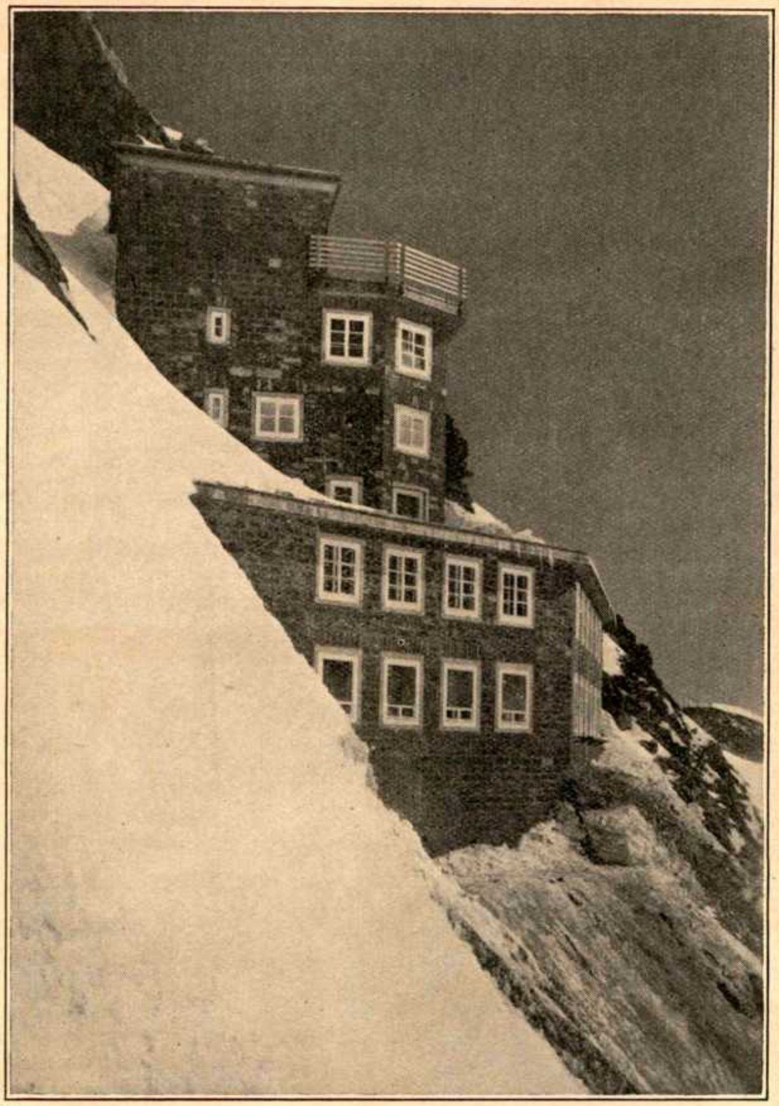

Photo.] [*R. Schudel, Grindelwald.*

FIG. 2.—Jungfraujoch Scientific Station from the west.

On the ground floor (Fig. 3) are an entrance lobby, cloakroom, six research-rooms (two of which each afford room for two working places), a workshop, a dark-room, store-rooms, a stable for animals, an electric power switch-room, and a fresh-water reservoir. On the first floor (Fig. 4) are situated a living-room, administrative bureau, nine single bedrooms, one four-bedded room, a bathroom, kitchen, and dark-room. In the tower, the lower floor is designed as a botanical laboratory and gives access to the flat roof of the main building; the middle floor affords quarters for the attendants, and the upper floor is devoted to the library, in which there is an optical projection apparatus. Above the library is an open-air terrace, which is partly roofed over as a protection against falling stones.

Electric power for heating, lighting, and cooking is obtained from the railway, and as a precaution against temporary failure of this supply an emergency lighting circuit is installed which is supplied with current from accumulators. Every research-room is supplied with running water and is fitted with a switchboard from which electric power may be obtained for experimental purposes at both high and low voltages. Valuable gifts of scientific apparatus have already been received from industrial firms.

The laboratory has been built with the view of encouraging research in both the physical and biological sciences; and it is certainly well adapted for the purpose. The benches in the research-rooms are ample and so arranged as to leave plenty of floor space available for the erection of special apparatus. The windows, which are double-glazed, are not very large; but in spite of this the general lighting of the rooms is extremely good: indeed, the glare from the snow-fields around renders the provision of sun-blinds essential. The research-rooms themselves are of good size, and it would be a mistake to suppose that only one research worker can be accommodated in each. Each is large enough to permit of work involving the co-operation of two or three persons. The building as a whole is, indeed, larger than might be anticipated, when the great difficulties that had to be faced in its construction are borne in mind.

The scientific station is designed to be complete in itself. Not only does it afford working space and sleeping quarters, but the kitchen also is adequate for the provision of meals for the occupants. The Hotel Berghaus is close to the laboratory, and at first sight it would possibly seem easier to take meals there. But it must be remembered that the number of tourists who are brought by the railway to the Jungfraujoch is very large, and that at the height of the season the hotel accommodation is liable to be taxed to the utmost.

It will be seen from Fig. 1 that the laboratory is quite separate from the hotel. It can only be entered from behind through a tunnel; and though this is connected with other galleries in the rock through which tourists can pass freely, it should not be difficult to keep out the inquisitive intruder: the research workers are therefore not likely to be inconvenienced materially by the tourist traffic.

For the purpose of meteorological observations the laboratory itself is not altogether ideal, since the rock face rises steeply above it and it only affords a free view in one direction. The snowfield on the summit of the Joch does not suffer from this disadvantage, as it commands an all-round view. For the meteorologist an even better site is to be found on the rocky peak, the 'Sphinx', the top of which is 400 feet above the laboratory. This can be reached from the Joch, and it is being rendered even more accessible for tourists by the Jungfrau Railway Co. It is hoped before long to establish a small meteorological station on this point.

The new research station is readily accessible from Interlaken by the Scheidegg and Jungfrau railways, and there will be no difficulty in carrying up both delicate and bulky apparatus. So short are the communications and so frequent the train service that little delay should occur if additional apparatus has to be procured during the course of a research, while telephonic communication with the Swiss universities and laboratories will be easy. The laboratory will be available for work all the year round, summer and winter alike. It may fairly be claimed that the disadvantages under which so many of the earlier high altitude expeditions laboured have now been overcome, and with the full laboratory facilities at their disposal research workers at the new station should be the better able to attack with success many problems which are as yet unsolved.

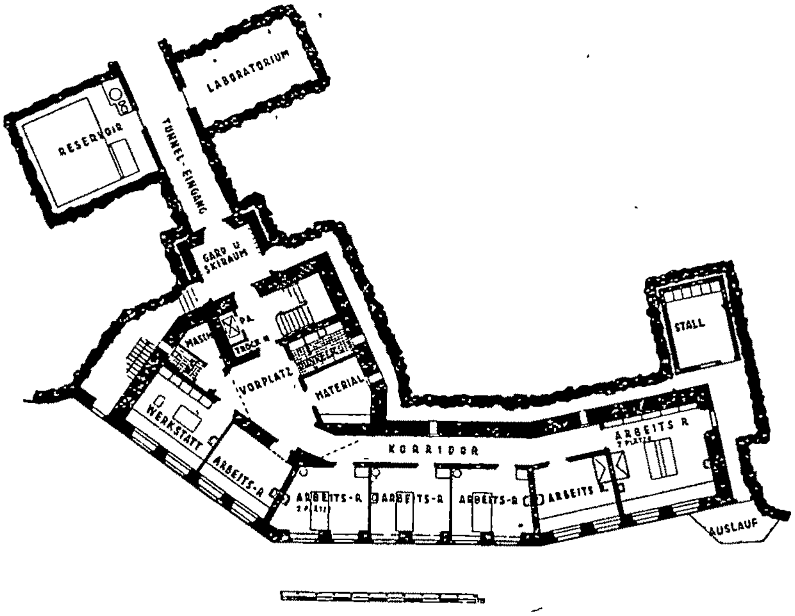

FIG. 3.—Plan of ground floor with research-rooms.

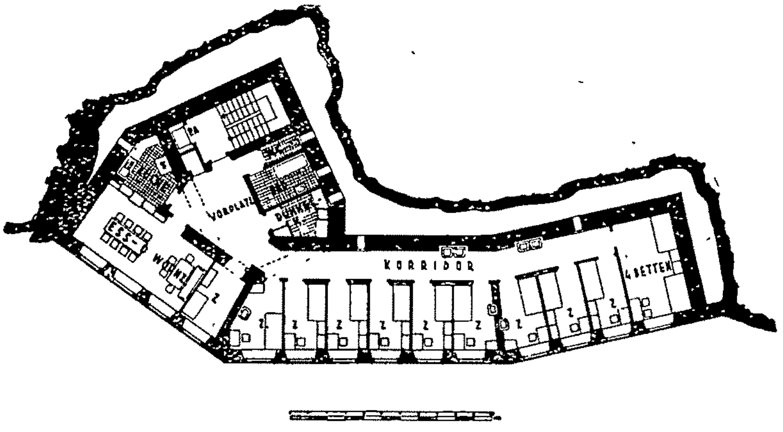

FIG. 4.—Plan of first floor with living-room and bedrooms.

It would, no doubt, have been an advantage if the laboratory could have been built at a still higher altitude; but no other point in the Alps so high as the Jungfraujoch can be reached with such ease; the Gorner Grat, for example, which can be reached by train from Zermatt, is more than 1000 feet lower. Though the altitude of the new scientific station may seem but moderate in comparison with the heights reached by mountaineers in recent years, it is a point of some interest to physiologists that genuine mountain sickness is by no means unknown amongst those who ascend to the Jungfraujoch from the lowlands and have had no time to become acclimatised. After all, the barometric pressure is only about 500 mm. of mercury at the laboratory.

The direction of the Jungfraujoch Scientific Station is vested in a council, consisting of a president, Prof. W. R. Hess, of the University of Zurich, and two representatives of each of the following bodies: the Swiss Naturforschende Gesellschaft, the Kaiser Wilhelm Gesellschaft zur Förderung der Wissenschaften of Berlin, the University of Paris, the Royal Society of London, the Akademie der Wissenschaften of Vienna, the Fonds National de la Recherche Scientifique of Brussels, and the Jungfrau Railway Company. There is in addition an executive committee, of which the officers are Prof. W. R. Hess, president; Prof. A. Kölliker, of Zurich, treasurer; and Prof. L. W. Collet, of Geneva, secretary.

Faraday as a Botanist.

By Dr. R. W. Butcher.

AMONG the Faraday relics at the Royal Institution is a small quarto book containing a collection of pressed flowers collected between 1850 and 1853, when Faraday was about sixty years of age. Apparently this book is very little known, and this seems an opportune time to describe it, as it shows that the great scientific investigator had no mean knowledge of his native plants, a fact not noted elsewhere.

The book is inscribed: "Michael Faraday to Joan Barnard" (his niece), and probably the collections were made when they were on holiday together. Each page is numbered; on the left-hand pages the specimens are mounted with gum, and on the right-hand pages quotations are sometimes written. Most of the plants are named both with the English and scientific names. The writing appears, for the most part, to be that of Mrs. Faraday, though whether all was written by her is doubtful. Mr. Evelyn Barnard thinks that the flowers were collected and named and the verses chosen by Michael Faraday and written in the book by Mrs. Faraday.

The collection falls into four periods. In July 1850, thirty-one specimens were collected at Norwood. In September 1850, fourteen were collected at Kingswood, Surrey; and probably at the same time, the box from Box Hill. Then follow ten plants unnamed and unlocated; these are spring woodland plants such as *Arum maculatum* and *Orchis mascula*. The last lot, six in number, were collected at Hastings in 1853. A full list will best illustrate Faraday's collecting activities. The names in square brackets have been added by me.

1. From Norwood, July 1850.

1. *Lathyrus pratensis*.
2. "*Anthyllis vulneraria*" [this is *Lotus uliginosus*].
3. *Lotus corniculatus*.
*4. *Lonicera periclymenum*.
*5. *Rosa canina* [*Rosa arvensis* also on same page].
*6. "*Rosa rubiginosa*" [this is *Rosa micrantha*].
*7. "*Hypericum perforatum*" [this is *Hypericum pulchrum*].
8. *Hypericum* [*humifusum*].
9. *Hypericum Androsæmum*.
*10. *Chrysanthemum leucanthemum*.
11. *Ranunculus flammula*.
*12. *Papaver rhœas*.
13. *Vicia Cracca*.
14. "*Fumaria*" [this is *Vicia hirsuta*].
15. *Potentilla Tormentilla*.
16. *Juncus* [*communis*].
17. *Digitalis purpurea*.
18. *Polygala vulgaris*.
19. [*Lathyrus montanus*].
20. *Lysimachia nemorum*.
21. *Lysimachia nummularia*.
22. *Scutellaria galericulata* (no specimen).
23. *Tamus communis* (no specimen).
24. *Chelidonium majus*.
*25. *Veronica Chamædrys*.
26. *Veronica officinalis* (no specimen).
*27. "*Veronica serpyllifolia*" [this is *Veronica montana*].
28. *Erythræa Centaurium*.
*29. *Anagallis arvensis*.
*30. *Campanula rotundifolia*.
31. *Asperula odorata*.

2. From Kingswood, September 1850.

*32. *Erica cinerea*.
33. *Erica tetralix* (no specimen).
34. *Calluna vulgaris*.
35. *Linaria spuria*.
36. *Bartsia Odontites*.
37. "*Senecio*" [this is *Solidago virgaurea*].
38. *Polygonum Persicaria*.
39. *Centaurea scabiosa*.
40. *Helianthemum vulgare*.
41. *Anagallis cærulea* [this is a dwarf *Veronica Buxbaumii*].
42. *Scabiosa arvensis*.
43. *Clematis Vitalba*.
44. *Achillea Millefolium*.
45. *Buxus sempervirens* (from Box Hill).
46. *Agrimonia Eupatoria*.
47. *Trifolium procumbens*.

3. Unnamed and Unlocated.

48. [*Orchis mascula*].
49. [*Arum maculatum*].
50. [*Anemone nemorosa*].
51. [*Allium ursinum*].
52. [*Lastrea Filix-Mas*].
53. [*Ornithogalum nutans*].
54. [*Hedera helix*].
55. [*Primula vulgaris*].
56. [*Anthriscus sylvestris*].
57. [*Hypnum molluscum*].

4. Hastings, 1853.

58. *Statice Armeria* (from Castle Hill).
59. *Ornithopus perpusillus*.
60. *Rumex acetosella*.
61. *Sedum anglicum*.
62. *Trifolium subterraneum*.
63. [*Erodium cicutarium*].

* With quotation.

There are several points of interest in this list. From Norwood there is a collection of plants from a district now covered with houses. Of the Surrey plants, the most interesting are *Hypericum Androsæmum* and *Veronica Buxbaumii*; the former because it is by no means a common plant, and the latter because it indicates how common this plant, introduced about 1835, had become. The other Surrey plants are recorded by Brewer in the "Flora of Surrey" as common. Apparently, Faraday also noted the difference between *Lotus corniculatus* and *Lotus uliginosus*, though he did not name the latter correctly. Of the Hastings plants, *Sedum anglicum* may be considered a first county record, as in the "Flora of Sussex" the earliest record is 1878.

Considering the literature available at that time, the naming of the plants is remarkably accurate; the mistakes are shown in the list and illustrate the collector's difficulties—difficulties with which some who remember their first attempts to name wild-flowers will sympathise.

The order of the plants in the book is probably the order in which they were collected, closely allied plants being put together when collected at the same time.

Quotations are written by the side of eleven of the plants and these are indicated in the list with an asterisk. Some quotations are assigned to their author, but most are anonymous.

My best thanks are due to Sir Robert Robertson (hon. treasurer) and to Mr. Cory (librarian) of the Royal Institution, for enabling me to examine the book, and to Mr. Evelyn Barnard, donor of the book to the Royal Institution, for information.

News and Views.

HIS MAJESTY THE KING has approved the following awards this year by the president and council of the Royal Society in respect of the two Royal Medals: Royal Medal to Sir Richard Glazebrook for his distinguished work in experimental physics; Royal Medal to Prof. W. H. Lang for his work on the anatomy and morphology of the fern-like fossils of the Old Red Sandstone. The following awards of medals have also been made by the president and council: Copley Medal to Sir Arthur Schuster for his distinguished researches in optics and terrestrial magnetism; Davy Medal to Prof. A. Lapworth for his researches in organic chemistry, particularly those connected with tautomerism and the mechanism of organic reactions; Sylvester Medal to Prof. E. T. Whittaker for his original contributions to both pure and applied mathematics; Hughes Medal to Prof. W. L. Bragg for his pioneer work on the elucidation of crystal structure by X-ray analysis.

WE print as a Supplement to this week's issue the evening discourse entitled "Beyond the Milky Way", delivered by Sir James Jeans on Sept. 29 during the centenary celebrations of the British Association. Starting with the star system of which we are a part, Sir James takes us outside it into the realms of interstellar spaces and the extra-galactic nebulæ, and in his characteristic and lucid manner leads us to a consideration of the hypothesis of the expanding universe. The extra-galactic nebulæ known to astronomers present a bewildering variety of size, shape and brightness, but after eliminating those which are not seen edge on, the remainder may be arranged in a single continuous sequence, beginning with spheres and ending with flat discs. This sequence is interpreted as showing evolutionary development from a mass of rotating and shrinking gas. The nebulæ are distributed fairly uniformly through space, and are regarded as condensations of a universal primeval gas. Recent observations have shown that the nebulæ are receding from the galaxy and from each other at speeds approximately proportional to their distances; the universe appears to be expanding like a balloon during inflation. This is in accord with relativity considerations, but it makes the ages of the stars considerably less than we have hitherto believed. The hypothesis of an expanding universe was dealt with in the British Association discussion which we printed as a supplement to NATURE of Oct. 24, and it also formed the subject of Sir Arthur Eddington's presidential address to the Physical Society delivered on Nov. 6. Sir Arthur pointed out that the theory of the 'expanding universe' can also be regarded as the theory of the 'shrinking atom', and he envisaged a cosmic being, whose body kept pace with the expanding intergalactic spaces, looking down on the atomic drama and watching the actors growing smaller and smaller and the action faster and faster until "One last microscopic blur of intense agitation. And then nothing."

SIR ARTHUR EDDINGTON'S presidential address to the Physical Society was entitled "The Expanding Universe". After a brief sketch of the system of spiral nebulæ, he described the necessity of introducing the cosmical constant 'lambda', and went on to show that the ideal universe postulated by Einstein some years ago is unstable. If initial expansion is set up, it will continually increase. From a study of the wave equation of the electron, Sir Arthur has recently found a theoretical value of the cosmical constant, and from this he deduces the following values. The equilibrium radius of the universe is 1068 million light-years, the number of electrons in it is $1 \cdot 29 \times 10^{79}$. Its total mass is $1 \cdot 08 \times 10^{22}$ times that of the sun. The recession due to the 'lambda' term is 528 km./sec. per megaparsec, in excellent agreement with the round number 500 km./sec. which has been adopted from observation. He concludes that the recession of the spiral nebulæ, indicated by the spectroscope, is a real one; others have suggested that the reddening of the light may arise in some other way. The universe doubles its radius in 1300 years, a space included within the limits usually assigned to geological time.

SIR ARTHUR EDDINGTON pointed out that this favours the intermediate scale of stellar life (of the order of ten thousand million years, rather than many millions of millions), a conclusion which he reached in another manner last year by considering the motion of the interstellar gas in our galaxy; it was found that this motion was unlikely to persist for the periods required by the longer scale. The intermediate scale permits the theory that stellar energy is derived from the transmutation of hydrogen into other elements, though the theory of the annihilation of atoms is still tenable. He made an interesting suggestion about the cosmic penetrating radiation. The only source which can be considered to be arranged symmetrically about the earth is the whole universe. These radiations go back to the early days of the universe, and have probably circuited it several times. Their wave-length is probably some four times as great as its primitive value, so that a correcting factor should be applied before making deductions from it as to the origin of the rays.

JOHANNES BOSSCHA, the centenary of whose birth falls on Nov. 18, was regarded as the leader of Dutch physicists. Born at Breda, he was initiated into physics by van der Willigen. In 1850 he entered the University of Leyden, and two years later took his degree with a dissertation on the differential galvanometer, his work being done in the physical laboratory at Leyden, then under the direction of Rijke. After a short stay at Berlin he became an assistant in the laboratory, where he did much work in connexion with the law of the conservation of energy, the e.m.f. of the Daniell cell and multiplex telegraphy. Ten years of his life were devoted to secondary and technical education in Holland and the provision of facilities for scientific studies. In 1873 he became a professor and in 1878 the director of the Polytechnic at Delft; in 1885 he was made secretary of the Dutch Society of Science at Haarlem. He also reorganised the Dutch Meteorological Service. He made original researches on the velocity of sound and on heat. Much of his later life was devoted to the study and editing of the correspondence of Huygens. He died in the spring of 1911 and an appreciation of his work by Kamerlingh Onnes was published in NATURE for May 25, 1911.

MANY of our readers must have seen with regret the announcement in the daily Press that a serious outbreak of fire occurred at the University of St. Andrews in the early morning of Nov. 3. We learn that considerable damage has been done to the new building which contains the chemical and physical laboratories of the United College of St. Salvator and St. Leonard. The entire roof of the physical laboratory and part of that of the chemical laboratory have been destroyed. Two large Hilger spectroscopes and other instruments used in physical research have been badly injured. A large amount of valuable apparatus has been completely destroyed as well as many chemical specimens illustrating Prof. J. Read's researches. It is remarkable that many specimens of the products obtained by the late Prof. Purdie and Principal Sir James Irvine have escaped. An unofficial estimate places the amount of damage, which is covered by insurance, at £10,000. Fortunately, the fire did not reach the chemical research laboratory at the north end of the block or the adjoining building, which houses the natural philosophy lecture rooms and museum, where much interesting historical apparatus is preserved.

THE Royal Photographic Society has arranged a series of annual exhibitions illustrating photography in the service of man. The third of the series was opened on Nov. 9 at the Society's house at 35 Russell Square, London, W.C.1. It is devoted to colour photography, and will remain open on each weekday from 10 A.M. to 5 P.M. until Nov. 28. Demonstrations of modern colour processes will be given at 7 P.M. on Nov. 18 and 25, on which days the exhibition will remain open until 9 P.M. In its historical section, the exhibition honours a host of scientific workers and inventors too numerous to mention individually. Overshadowing all the rest are the names of Clerk Maxwell and Ducos du Hauron, whose discoveries form the foundation of most of the practicable methods of colour photography. The most brilliantly colourful section of the exhibition represents the four main photomechanical processes: collotype, half-tone photogravure, and photolithography. Great progress, has been made in simplifying colour printing during the last thirty years. Coloured prints of great beauty were produced many years ago, but they were very costly owing to the large number of printings necessary for each; twelve, sixteen, or even more different printings being often made. To-day, exquisite replicas of paintings often take no more than seven printings, and even this is deemed a very complicated process. Most modern colour reproductions are made with three or four printings.

THERE is in one of the showcases at the exhibition a specimen page of a popular daily picture paper printed in colour. This seems like prophecy. How long will it be before our great daily papers print their pictures in colour? Photolithographic reproduction in colour by offset printing is now capable of yielding an enormous output, and can be employed on comparatively rough paper. The methods of colour photography which may be used by the amateur are also very well represented. Mosaic screens of all kinds and transparencies obtained with many of them are shown. Then there are examples of various apparatus employed for making three colour-separated negatives, including cameras in which the three exposures are made simultaneously, and 'repeating backs' which allow negatives to be made consecutively. The automatic repeating back is said to make three consecutive exposures in a total time of about one second. This apparatus is now employed for recording in clinical medicine. There is a great deal more: two-colour photography, Lippmann photography, colour reproduction by diazo processes, colour cinematography, all of great interest. The exhibition is probably one of the finest of its kind which has ever been produced in Great Britain.

IN a paper read to the Illuminating Engineering Society on Oct. 30, Mr. P. Good discussed the lessons to be learnt from the recent flood-lighting display. He considers that the cost of flood-lighting was not an extravagance. He pointed out that a sum of £50,000 would equip and endow in perpetuity the proper lighting of the façade of the National Gallery. Another way of considering the matter is this: one per cent of the expenditure of the B.B.C. on music and entertaining would maintain the flood-lighting carried out in London for the International Illumination Congress this year for a whole year, and provide illuminated fountains in Trafalgar Square as well. Mr. Good made two useful suggestions for utilising the advertising value of flood-lighting. He advocated that buildings, some hospitals, for example, which are at present defaced by advertisements for the purpose of raising money, should instead invite the advertiser to paint and flood-light their building so that it makes an attractive picture. The advertiser might be permitted to have a very small notice invisible to everyone except those close by, and be left to advertise in the Press what he had done. Mr. Good's second suggestion was that as there are many streets in London and its suburbs with bare plots of land utterly disfigured with advertisement hoardings, these should be removed and the advertisers could turn the waste-land into little gardens with small notices stating who had provided them. Mr. Good is certain that the lighting engineer, with the illimitable possibilities of flood-lighting, now has an opportunity for developing a new technique of advertising to replace the present blatantly self-assertive methods.

ACCORDING to a dispatch from the Peking correspondent of the *Times* in the issue for Nov. 4, it has now been established to the satisfaction of the members of the Geological Society of China that Peking man was capable of fashioning and using stone implements with considerable skill. At an early stage in the investigation of the cave of Chou Kou Tien, the discovery of a piece of quartz not of immediately local origin was considered by Dr. Andersson to be evidence of the possibility that the early inhabitants of the cave used stone for implements; but a search prosecuted continuously for four years failed to produce further support of this view. It would appear, however, that artefacts in considerable number have now been found in the cave, as well as evidence of the use of fire. These artefacts have been submitted to a close examination, with the result already mentioned; they have also been accepted by the Abbé Breuil, who is now on a visit to China. He is said to regard them as indicating that life was intelligently organised at the time of Peking man, who must have had a much more primitive predecessor. This can only mean that the implements are relatively advanced in type. This is confirmed by Prof. Elliot Smith's letter to the *Times* for Nov. 5. He says that he is informed that the implements are well-shaped and not unlike the Chellean type of Europe. Prof. Elliot Smith adds that the new discoveries are due to Mr. W. C. Pei, the young Chinese palæontologist to whom we owe the discovery of the skull in December 1929. Further details and a more precise indication of the character of the implements will be awaited with interest. The close associations of a specific type of implement with this early type of man, in conditions which admit of more or less precise geological dating, still further enhances the significance of Peking man.

DR. MARGARET MEAD, of the American Museum of Natural History, sailed in the middle of August from New York for New Guinea, where she will spend two years in ethnographical field work. Dr. Mead is accompanied by her husband, Dr. Reo Fortune, who will investigate the religious and social organisation of certain tribes, on lines parallel to those to be followed by Dr. Mead in her study of the women and children and the attitude of the sexes respectively to certain matters of cultural and biological import. Dr. Mead will also be engaged in the collection of notes and specimens to be used in the preparation of models for installation in the South Sea Hall of the American Museum. These models will be similar to those of the inhabitants of the Admiralty Islands which have been set up as a result of Dr. Mead's recent expedition to Melanesia and are described in *Natural History*, vol. 31, pt. 5. In the same issue, Dr. George C. Vaillant, assistant curator of Mexican archæology, describes four very remarkable and instructive models of temples in Central America which have been presented to the Museum, two through the good offices of the secretary of the Trustees, Mr. Clarence L. Hay, one by the Carnegie Institution of Washington, and one by the Government of Mexico. The temples are representative of the characteristic cultures of Central American archæology, one being a model of Uaxactun E-vii-sub., the oldest Mayan temple yet discovered, the others, models of the Toltec pyramid of the sun of Teotihuacan, the Aztec temple of Teopanzalca, and the Totonac temple of Tajin, Vera Cruz. The advantage of these models in revealing the qualities and beauties of Central American architecture and art to the untrained eye is immediately apparent from an inspection of the photographs with which Dr. Vaillant's article is illustrated.

DR. RICHARD WOLFRAM, of Vienna, gave a lecture, illustrated by lantern-slides, on the sword dances of Austria to the English Folk Dance Society at Cecil Sharp House on Nov. 4. Dr. Wolfram dealt with these dances with special reference to their origin and meaning. As generally understood, the dances are regarded as survivals of a ritual dance, related to the fertility cult, in which is represented the sacrifice of the principal performer. Dr. Wolfram, however, maintains that they are to be attributed rather to the tendency of young men to form secret societies. Hence he relates them to the ceremonial of the secret initiatory rite. In this connexion, he directed attention to the morris dance, which means the dance with blackened faces, the dancers with blackened faces representing the army of the dead, just as the troops of children who beg at festival times are also to be regarded as representing the army of the dead. Dr. Wolfram laid considerable stress on the similarity which he finds underlies the English dances and those found throughout the Germanic peoples.

ONE of the most interesting exhibits at the Faraday Centenary Exhibition at the Albert Hall was a huge new valve manufactured by the Metropolitan-Vickers Electrical Co., Ltd. It stands ten feet high, is fourteen inches in diameter, and weighs more than a ton. Its water-cooled steel anode weighs 3 cwt., and hydraulic jacks are required to facilitate demounting and accurate assembly. Its filament current is approximately 500 amperes, and, according to the *Metropolitan-Vickers Gazette* for November, its filament emission of 160 amperes represents the almost inconceivable electron flow of three hundred thousand billions of electrons per second. It was built for operating the main transmitter at the Rugby G.P.O. radio station, where it will replace a bank of fifty high-power valves. No glass is used in its construction, only steel, copper, and porcelain. The possibility of making such a huge valve was first suggested by the discovery in the research laboratory of the company that oil distillates had remarkable properties. They can be boiled at a fairly high temperature without decomposition, and yet at room temperature their rate of evaporation is so small that they can be placed inside a radio valve without impairing the vacuum. Its low volatility proved that an oil distillate is an ideal liquid to replace the mercury of the vapour pump. Using this liquid, an exceedingly high vacuum is obtained even at the highest power input. In the event of repairs being necessary the valve is completely demountable. Only ordinary engineering tools are used to make repairs. The manufacture of valves of 500 kilowatts, the largest in the world, has now been demonstrated and the possibility of constructing even larger valves has been proved. In fact we may say that the transmission of power on a large scale by radio has been shown to be practicable. These large radio valves mark the beginning of a new era in engineering practice.

IN a leading article in the *Engineer* for Oct. 30 a strong appeal is made for increased support from the shipping and shipbuilding industries for the Froude Laboratory and National Experimental Tank at the National Physical Laboratory, Teddington. The annual cost of the Laboratory and Tank is about £12,000, of which £7000 is earned in fees, while, up to now, the Department of Scientific and Industrial Research has given pound for pound to all sums contributed by the industry for research. With this assistance, the sum required from shipbuilders and shipowners is £2500. In the course of the article, figures are given as to the number of designs submitted and the numbers in which improvements were made. Out of thirty tests made in 1930, no fewer than five brought about an increase in efficiency of 20-30 per cent. Moreover, there are no signs of slackening in the efforts of other nations. Improvements have been made in the tanks at Hamburg, Berlin, and Spezia, while new tanks have been built at Rome, and in Holland and the United States. The new tank in America is 1920 ft. long. It is true that shipping and shipbuilding are both suffering severely from the decrease in the trade of the world, but Great Britain and Northern Ireland still own twenty million tons of shipping, against the four million tons of Germany, and the 9,500,000 tons owned by France, Holland, and Italy collectively. Where so much is at stake it does not seem an unreasonable hope that so small a sum as £2500 will be forthcoming.

THE Lord Mayor's Show is an annual civic event in London of popular interest. This year it had an added interest in that, at the request of the new Lord Mayor, Sir Maurice Jenks, the pageant illustrated the progress of industry aided by science. The leading car was from the National Institute of Industrial Psychology and bore at its foot a large oil-can, "Industrial Psychology oils the wheels of Industry". Then came three cars illustrating the radio industry and showing a modern 'radio' home, the earth girdled by radio, and a symbolic tableau including the arms of the Radio Manufacturers' Association. The cinematograph industry was represented by cars portraying by tableaux the sciences which have contributed to its development, early apparatus, a modern film studio, and modern picture and sound production. The transport industry was illustrated by early and modern forms of bicycle and motor-car, including *Bluebird*, the motor-car in which Sir Malcolm Campbell made the land speed record, and *Miss England II.*, the motor-boat in which Mr. Kaye Don made the present water speed record. The Gas Light and Coke Company had cars showing the scientific application of gas in industry and in the home; one car carried a gas-heated annealing furnace in operation. The British Electrical Development Association, Inc., was mainly responsible for a car representing symbolically light, heat, and power, the three principal applications of electrical energy. Modern electrical communications were represented on a car by Imperial and International Communications, Ltd., designed to demonstrate the cable and wireless links maintained by this company, which owns more than half the world's submarine cables and a widespread system of wireless services. The Lord Mayor's Show this year was a useful piece of propaganda on behalf of science in industry.

IN a pamphlet entitled "The Social Function of Science", Prof. C. H. Desch directs attention to the need for greater effort to make the influence of science felt in the world of citizenship and to bring home to the public the value of the services which science, rightly interpreted, can render to the community. The continuous subdivision of science both in research and in teaching not only results in excessive specialisation, but also widens the gap between the physical and the biological sciences. Prof. Desch, asserting the importance of developing real social sciences, points out that the evolution of these sciences will assist in a synthesis or union of the sciences which will remove the isolation of the specialist in different fields and promote contact with life. As illustrating the need for science in national life, Prof. Desch refers to the growing recognition of social well-being as the true object of industry and the need for scientific minds, free from party prejudices, to bring into the political field the ideas of international co-operation which in industry and economics have already made rapid progress where scientific principles have control. Similarly, scientific methods of thought might well be applied to questions of finance, particularly to distinguishing between positive and negative values in regard to wealth, etc., and there is still great disproportion in Great Britain between the control of industry exercised by technical as compared with purely financial or commercial interests. Scientific men cannot disclaim responsibility for the purposes to which the knowledge they acquire is applied, and the application of scientific method to the study of social facts is urgently needed if society is to be preserved from anarchy. The problem is chiefly a matter of education and of research. Scientific workers are called upon to co-operate in an attempt to interpret to

Supplement to NATURE

No. 3237 NOVEMBER 14, 1931

Beyond the Milky Way.*

By Sir JAMES JEANS, F.R.S.

OUR earth is one of a system of nine planets which, with millions of smaller bodies—asteroids, comets, and meteors—circle round the sun; our sun is one of a system of millions of stars which circle about one another; this star-system is one of millions of star-systems—and here, so far as we know, the sequence ends abruptly. These star-systems are the biggest objects known to science; there is nothing beyond them except the great universe itself. They form the largest subdivision of the universe, and it is from this circumstance that they derive their special importance to science.

THE GALACTIC SYSTEM.

Our own special system of stars—the system of which our sun is a member—is called the galactic system, because it is bounded by the Milky Way. In shape it is known to be somewhat like a disc or a coin or a cart-wheel. Perhaps the last of these three comparisons is the best, because it has recently been found that the whole system is rotating. Early investigators, Sir William Herschel in particular, believed, for inadequate reasons, that the hub of this wheel must be somewhere near the sun; we now know that it is so remote that even the brightest stars near the hub are invisible to our unaided eyes. Indeed, we can see no stars which are more than about 3000 light-years away, while the hub of this great wheel of stars is probably something like 40,000 light-years away. We still do not know the size of the wheel with any approach to accuracy, but its diameter is probably of the order of 200,000 light-years.

This great wheel is held together by the gravitational attractions of the different stars of which it is composed. As a consequence the outermost stars move most slowly and take the most time to perform a complete revolution, just as in the solar system the outermost planets move most slowly and take longest to describe their orbits round the sun. The sun probably moves round the hub at about 200 miles per second, and requires something over 200 million years to perform a complete revolution.

We can estimate the mass of the wheel by calculating the gravitational pull it exerts on the sun to keep this from flying off into space. It is found that this mass is certainly more than that of 100,000 million suns, and may quite possibly be twice, or even four times, this. Probably the greater part of it represents matter in the form of stars. If so, as the average star has less mass than the sun, the galactic system must contain well over 100,000 million stars. Actual star-counts confirm this estimate.

EXTRA-GALACTIC SYSTEMS.

In the early days of astronomy the galactic system was assumed to be the only system of stars in the sky. Then it began to be conjectured by Kant and Herschel that it was only one of innumerable systems. Recent research has confirmed this conjecture very fully. If you look to the north of the star Beta in the constellation of Andromeda you will, if your eyesight is good, see a faint, hazy patch—the Great Nebula in Andromeda. It looks at first like diffused starlight—as though a bit of the Milky Way had broken loose and wandered off to the south. The astronomer Marius described it as looking like candle-light seen through a horn. When this vague patch of light is viewed through a powerful telescope a certain amount of detail begins to appear. But to study it properly we must photograph it, with an exposure of many hours. We then find that the nebula is far larger than it appears either to the unaided eye or on looking at it through a telescope; roughly speaking, it covers twenty times as much sky as the full moon. The part we can see with the unaided eye is only a small central region—a comparatively bright fuzzy mass. Coiled round this is a detailed structure which lies completely hidden until it is brought to light by a long exposure photograph (see Fig. 1). Just as, in 1609, Galileo's tiny telescope broke up the Milky Way into separate points of light which he at once identified as stars, so modern high-power telescopes break up the outermost regions of this nebula into separate points of light, which we can identify as stars (see Fig. 2). We may be sure they are stars, because many of them show the same peculiarities and characteristics as the stars of our own system; among them we recognise variable stars of regular Cepheid type, irregular variables, helium stars, and novæ. Many of these special types of stars are so peculiar, so uniform in their behaviour, and so similar to one another, that we can estimate the distance of the nebula from the apparent faintness of the examples we find in the nebula. According to Dr. Hubble's most recent estimate, its distance is such that its light takes just over 800,000 years to reach us.

---

* Evening discourse delivered before members of the British Association in the Central Hall, Westminster, on Sept. 29.

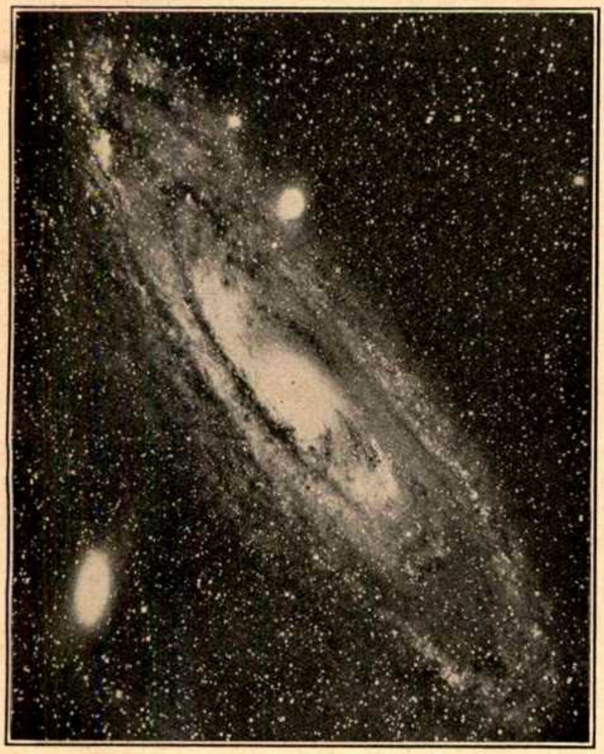

FIG. 1.—The Great Nebula (M 31) in Andromeda.

We can no longer doubt that, in its outer parts at least, this great nebula is a system of stars essentially similar to our own galactic system. We recognise the cart-wheel shape at once, the brighter fuzzy centre, the only part we can see without high telescopic power, forming the hub. The spectroscope shows that this cart-wheel too is in rotation—again like our galactic system. But it is spinning much faster; while our system requires about 200 million years for a complete revolution, this nebula gets round once every 17 million years or so. Its greater agility is due in part to its smaller size; it has only about a quarter of the diameter of the galactic system—50,000 light-years as against perhaps 200,000 light-years.

Again, this structure can be weighed by calculating the force which the system as a whole must exert on its outermost members to restrain them from running off at a tangent into space. We find that the weight of the whole nebula is quite small compared with that of our galactic system—about 5,000 million suns, as against perhaps 200,000 million suns for the galaxy.

These two cart-wheels are not the only such systems in the sky; millions of others can be observed. They are the objects we commonly describe as extra-galactic nebulæ.

A random collection of such nebulæ may seem at first to exhibit a bewildering variety of size, shape, brightness, and constitution, but a scientific study soon reduces them to law and order. Size and brightness are found to go together, and variations in both originate mainly in differences of distance. The nebula which appears small also appears faint, and does both merely because it is far away. If we could put all the extra-galactic nebulæ in a row at the same distance from us we should see that they were all of about the same size and the same brightness. Here and there in the sky Nature performs this experiment for us. An example is shown in the upper half of Fig. 3, where we find a cluster of nebulæ which we believe to be physically related, because they all show approximately the same motion in space, like a flock of birds. The members of such a flock are presumably all at about the same distance, and it is significant that they all appear to be of about the

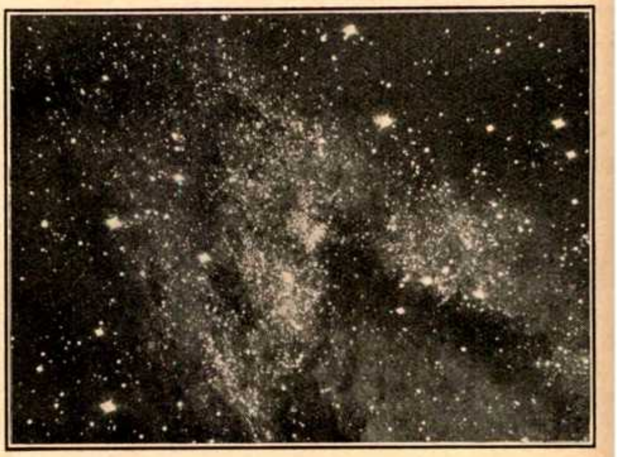

FIG. 2.—A small part (left-hand top corner) of the Great Nebula (M 31) in Andromeda, showing separate stars.

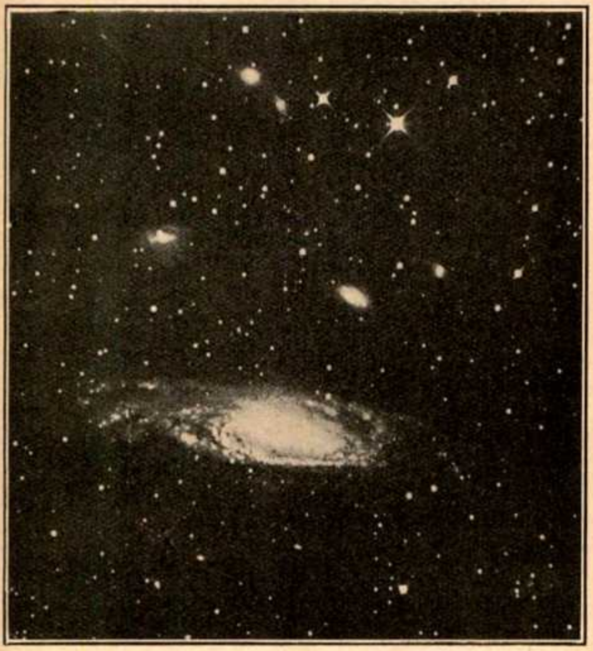
same size and brightness. The nebula in the lower half looks ten times as big because it is about ten times as near. The nebulæ still appear to be of very different shapes, but this is partly because they are differently oriented with respect to ourselves; we see them along different lines of sight.

We can avoid all complications caused by the different orientations of the nebulæ by the very simple device of rejecting all those which are not seen edge on, and confining our attention to those that are. We can do this quite recklessly, as some two million nebulæ can be seen in all.

In this way we can eliminate all the purely geometrical effects arising from differences of distance and of orientation, and are left with real physical differences of shape and constitution. We find that by far the greater number of our edge-on nebulæ can be arranged in a single continuous sequence (cf. Fig. 4); it is in brief a sequence which begins with spheres and ends with flat discs, although other features besides shape change as we move along it. The nebulæ at one end of the sequence consist solely of round fuzzy masses, and even the most powerful telescope shows no stars in these. About half-way along the sequence stars first begin to appear—in the outer edges of the nebulæ. Then, further along, come nebulæ similar to the Great Nebula in Andromeda, which consist of a comparatively small central fuzzy mass, surrounded by vast crowds of stars. At the extreme end of the sequence we have pure clouds of stars such as our own system. The comparison of the cart-wheel remains quite a good one throughout the second half of the sequence, because the nebulæ here generally have a thick central projection, the hub of the wheel, while the rest of their structure is flat.



Mt. Wilson Observatory.

FIG. 3.—Cluster of nebulæ in Pegasus and the nebula N.G.C. 7331, which looks ten times larger, because it is about ten times nearer.

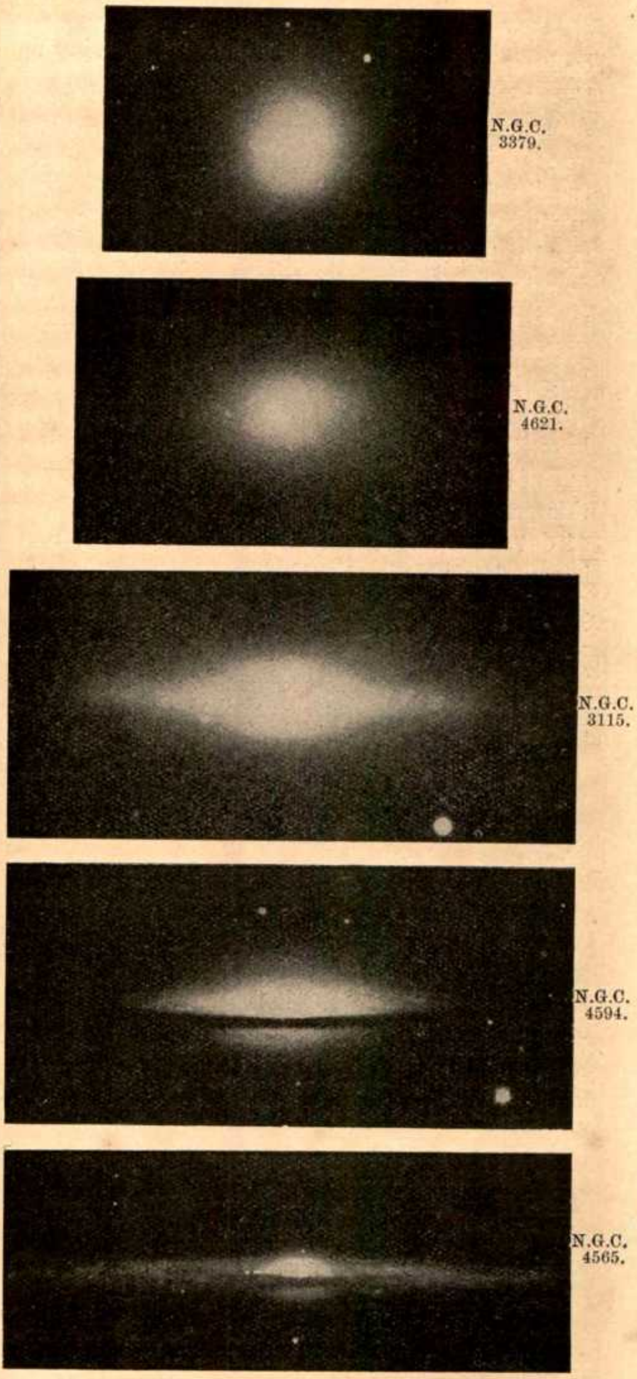


FIG. 4.—A sequence of nebular configurations providing a sort of cinematograph film of the birth of stars.
From "The Universe Around Us", by courtesy of the University Press, Cambridge.

In brief, our sequence is one of nebulæ arranged in order of flatness, and this suggests a simple theoretical interpretation of the sequence.

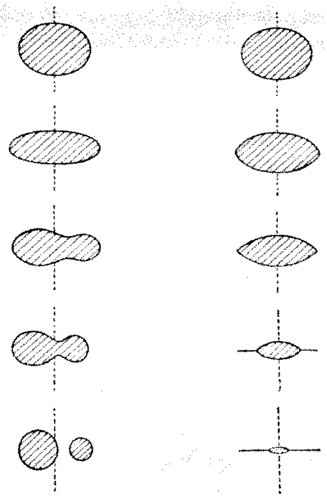
We know how increasing the speed of rotation of a body results in a flattening of its shape. The ordinary Watt governor provides an obvious instance—as the engine runs faster it flattens out. Astronomy provides innumerable instances of the same effect. The sun rotating only once every twenty-six days is an almost perfect sphere. The earth, rotating more rapidly, although still very slowly, is slightly flattened, so that we usually describe it as orange-shaped. Jupiter rotates still more rapidly—once every ten hours—and is much flatter in shape. It is natural, then, to try to interpret our sequence of nebulæ as one of bodies which are rotating at different speeds. As we know that the speed of rotation of a body increases as it shrinks, it seems likely that we may interpret this sequence of nebulæ as one of different stages of development or evolution. If this conjecture is sound, a nebula starting with little rotation at first and shrinking in size would gradually increase its speed of rotation as it shrank, *and would move steadily along the sequence as it did so.*

The way to test this conjecture is to calculate for ourselves how a mass of rotating gas would change in shape as it condensed and shrank. Although the mathematical analysis is not simple, and cannot be very precise, it is, I think, fairly conclusive; we find that the evolution of a mass of rotating and shrinking gas would be represented almost exactly by passage along the sequence.

THE BREAKING-UP OF THE UNIVERSE.

Let us look at the problem in its broadest aspects. Mathematical cosmogony suggests that the shapes of astronomical bodies are moulded by three main agencies, in addition, of course, to the universal and all-pervading forces of gravitation. These three are (1) rotation, (2) tidal action, (3) gravitational instability. The general effect of all three is to break up large bodies into smaller, so that the universe tends to evolve from a few large bodies to many small ones.

Let us consider these three agencies in turn, beginning with rotation. The simplest example of its action is to be found in the formation of binary stars. As a rotating star shrinks, its rotational momentum must remain always the same throughout its continual diminution of size, so that the star finds it necessary to push ever more and more of its mass out, away from its axis of rotation. First it flattens itself and so pushes its equatorial regions away from its axis. With further shrinkage this expedient becomes inadequate, and the mass stretches itself out into a torpedo-shaped body, spinning about its shortest diameter, the ends of this torpedo being, of course, farther from the centre than if it had retained its symmetrically flattened form. When this expedient also fails, the torpedo develops a sort of waist round its middle, in this way pushing even more of its substance to its own ends; this waist gets thinner and thinner until finally it fades into nothingness, and we are left with two detached bodies revolving about one another—the normal binary star. Rotation has broken one star into two (see Fig. 5*a*).



(*a*) liquid (*b*) gas

FIG. 5.—Sequence of configurations of rotating masses of liquid and gas.

From " The Universe Around Us ", by courtesy of the University Press, Cambridge.

Mathematical theory shows, however, that a purely gaseous mass could not break up in this way; the process we have described only occurs in bodies whose central regions are less compressible than a gas. When a purely gaseous body shrinks, and so increases its speed of rotation, the first result is again for it to become flatter in shape. But it never assumes the elongated torpedo-shape; its equator merely spreads out more and more until finally it becomes a sharp edge. The mass of gas has now assumed the shape of a double-convex lens. After this stage has been reached the mass cannot adjust itself to further shrinkage by a mere change of shape. It is like a fly-wheel which is rotating too fast for safety. With any further increase of speed the fly-wheel bursts, and, in the same way, the rotating mass of gas scatters matter out from its equator into its equatorial plane. This is precisely what we see in our sequence of nebulæ (compare Figs. 4 and 5*b*), and it suggests that, up to this point of their evolution at least, the nebulæ are rotating masses of gas.

The second of our three principal agencies is tidal action. Just as the sun and moon raise tides in our oceans, so any two astronomical bodies which come sufficiently near to one another raise substantial tides on one another's surfaces. We have seen how the earth's orange-shaped flattening, due to its rotation, is only the first link in a long and varied chain of configurations. So with tidal action—the feeble tides which the sun and moon raise in our oceans are only the first link in an equally long and varied chain of phenomena. As the tidal forces become more intense, simple tidal waves give place to huge excrescences of matter, and finally to terrific distortions of figure, which may end in the body being torn into two or more pieces by the tidal pull of its near neighbour.

Surrounding every massive body there is a danger-zone whose radius can be calculated. Any smaller body enters this danger-zone at the peril of its life, for there are large chances that it will be torn to pieces, and these chances become a certainty if it stays inside the danger-zone long enough. The simplest instance of the result of such action is probably to be found in the earth-moon system. Although this is far from certain, it is likely that the earth and moon originally formed a single body which was torn into two as a result of the tidal action of a larger body, probably the sun. A more striking instance is provided by Saturn's rings. These are known to consist of myriads of infinitesimal moons, each describing an orbit round Saturn at the speed appropriate to its distance. They are believed to be the broken fragments of a single moon which fell within the danger-zone surrounding Saturn and stayed there. The tidal forces of Saturn would continue to break up the unfortunate moon until each individual piece was small enough to resist their disruptive tendency—for the cohesive attraction varies as the square of the linear dimensions, while the disruptive tendency of tidal action varies as the fourth power. The asteroids—the swarm of tiny planets which circle round the sun between the orbits of Mars and Jupiter—may owe their existence to a similar occurrence. We have further instances of the same effect in the few observed cases in which comets have been broken into several pieces, or into swarms of meteors, by the tidal pulls of the sun or Jupiter.

The more weakly a body is held together, the more feeble the tidal forces which are needed to tear it asunder. Now by the time that a rotating mass of gas has reached the critical shape of a lens with a sharp edge, the matter of its equator is so weakly held that any tidal pull, no matter how feeble, will suffice to break it up. The equator of the nebula is in the state of a fly-wheel which is just about to burst; it will break first at its weakest point. The tidal action of distant bodies will raise tides on the equator of the rotating nebula, and the point at which these tides are highest will be the weakest point, since the gravitational hold of the nebula is feeblest there. Generally there will be two points of high tide antipodally opposite to one another, and when the nebula breaks up it will be through matter streaming away from these; thus we ought to see a lens-shaped mass with matter streaming out of two antipodal points of its equator. This is exactly what we do see when we view nebulæ full on, although our sequence of nebula (Fig. 4) naturally could not show it, because we saw them edge-on. Whenever, as for instance in Fig. 1, we can study the ejected matter in detail, it shows a marked tendency to form two symmetrical streams.

The third agency, gravitational instability, is the instability which must necessarily affect a mass of gas spread uniformly and acted on only by the mutual gravitational attractions of its molecules. The theory of its action is very simple. We know that every system tends to pass to a configuration of stable equilibrium in which its potential energy is a minimum. Now when a gas is spread uniformly through space, its gravitational potential energy is not a minimum but a maximum; it can fall to innumerable other states, all of which will have lower total energy. The process of so falling consists physically in the gas forming condensations and aggregating about these.

Mathematical theory not only shows that this process must occur; it also provides a formula giving the mass of each aggregate. Thus it is easy to test whether any group of bodies was formed by gravitational instability or not; we need only calculate the masses predicted by theory, and compare them with the observed masses of the actual bodies. Perhaps the planets of the solar system provide the simplest example of bodies formed by gravitational instability. It seems probable that a passing star pulled out a long filament of matter from the sun by its tidal action, and that gravitational instability then moulded the matter of this filament into the present planets. To test the conjecture, we calculate the masses of bodies which would be formed in this way; we find that they agree closely enough with the actual masses of the planets.

Still another example of the action of gravitational instability can be seen in the nebulæ we have been discussing. When a rotating nebula throws off streams of matter from its equator, this matter will at first be uniformly spread in filaments lying in the equatorial plane. These are not in stable equilibrium ; they can lessen their potential energy by forming into condensations, and accordingly do so. These are the condensations which we see gradually forming in the nebulæ as we pass along the sequence, and which we believe to be stars in the making. Again we can test our conjecture by calculating the masses of the condensations as predicted by theory; again we find that these agree well enough with the observed masses of actual stars.

We may, then, be fairly confident that this is the way the stars come into being ; the sequence of nebular configurations shown in Fig. 4 is, in effect, a sort of cinematograph film of the birth of the stars. We see rotation resulting first in a flattening of figure and then in a break-up of the nebula, tidal action determining the mode and place of this break-up, and finally gravitational instability carving up the ejected matter into stars. We notice that all the three principal cosmogonic agencies are called into play to bring the stars into being.

It cannot be claimed that this is the whole story of the evolution of the spiral nebulæ, since the spiral arms spread farther into space than can be accounted for by the centrifugal effects of rotation alone. There must be other factors at work, and these we do not yet understand ; the formation of the spiral arms remains a mystery. Possibly the theory of relativity may provide an explanation in time, but it has not done so yet.

Nevertheless, the agreement between theory and observation is good enough for us to feel on fairly safe ground in tracing the evolution of the universe back from stars to nebulæ. But how did the nebulæ themselves come into being ? The conjecture which at once comes to the mind is that the nebulæ may have been formed by the same process as the stars ; just as the stars came into being as condensations in a tenuous uniformly spread gas —the outer fringes of the nebulæ—so the nebulæ may themselves have previously come into being as condensations in an earlier mass of uniformly spread tenuous gas, the agency this time being gravitational instability acting alone. This can never be more than a conjecture, but, as we shall now see, there are strong arguments in its favour.

We have already seen how differences in size and brightness between nebulæ of the same shape are almost entirely due to a distance effect. In other words, the faintness of a nebula gives us a measure of its distance. This and other methods of a somewhat similar kind make it possible to estimate the distances of all nebulæ, even the very faintest, with fair accuracy. The faintest which can be observed photographically in the 100-inch telescope prove to be at the amazing distance of about 140,000,000 light-years. Dr. Hubble finds that the two million nebulæ which lie within this distance are fairly uniformly spaced at about 1,800,000 light-years apart. We can construct a model by taking apples and spacing them at about 10 yards apart until we have filled a sphere a mile in diameter. This will use about 300 tons of apples. This sphere is the fragment of space we can see in the 100-inch telescope ; each apple is a nebula containing matter enough for the creation of several thousand million stars like our sun ; each atom in each apple is as big as Betelgeux, with a diameter slightly larger than that of the earth's orbit.

The circumstance that the nebulæ are found to be fairly uniformly distributed through space gives a certain *a priori* plausibility to the conjecture that they may have originated from a primeval gas spread uniformly through space. But the real argument in its favour is that once again we can calculate the masses of the condensations that would form under the influence of gravitational instability, and once again we find that each condensation would have something like the same mass as the observed nebulæ. Or, to put the same thing in another way, the conjectured primeval gas would break up into condensations at distances apart comparable with the 1,800,000 light-years which Dr. Hubble finds for the average distances of the actual nebulæ. Thus although, from the nature of things, we can never know the truth for certain, there are good reasons for conjecturing that the nebulæ came into existence as condensations formed by a primeval gas which was spread uniformly, or at least with some approach to uniformity, throughout space.

Cosmogony presents us with a picture of the evolution of the universe—a cinematograph film—in which big bodies continually break into smaller ; the film shows the one for ever changing into the many. We see, conjecturally at least, one primeval gas producing millions of nebulæ, each nebula then producing millions of stars, many of these stars breaking up into binary or multiple systems, or perchance changing into a solar system and producing millions of planets, comets, and meteors. Even this is not the end of the story, for planets may break up and form satellites, satellites may break up and form rings of tiny moons, such as we see surrounding Saturn. The debris of all this breakage may form comets, and these may in turn break up into showers of meteors—tiny objects often no larger than a pea which we describe as 'shooting-stars' when they hurl themselves to death in our atmosphere and suffer still further break-up into their constituent atoms.

THE SCATTERING OF THE UNIVERSE.

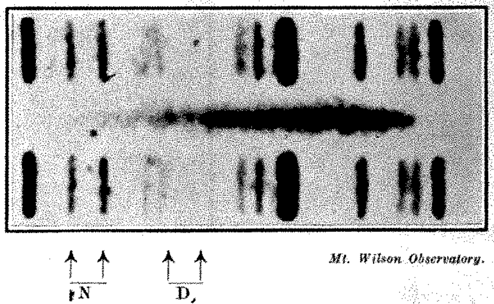
It might be thought that after all this breakage had occurred, the attractive forces of gravitation would tend to drag the broken fragments together again. The exact reverse appears to be the case. Not only is the substance of the universe for ever being broken into smaller pieces, but these pieces for ever tend to scatter farther and farther apart.

To take the example nearest home, the earth is for ever driving the moon farther away, through the agency known as tidal friction. When we watch the waves of the sea breaking against a sea-beach or a headland, we may reflect that their impact is not only slowing down the earth's rotation and so lengthening the day—it is also lengthening the month by driving the moon farther away from the earth. Incidentally it is also, through the solar tides, driving the earth farther from the sun, and so lengthening the year as well.

Again, every ray of sunlight that enters our eye carries mass with it; eight minutes previously this mass was part of the mass of the sun. Every second the sun loses more than four million tons of mass, in the form of sunlight and sun-heat. As the result of this continual loss of mass, the sun's gravitational hold on its family of planets for ever weakens and these are driven farther off into space. The earth's orbit round the sun is not so much like a circle as like a coiled watch-spring—a spiral path for ever receding into the cold and dark of space.

The same tendency affects the galactic system as a whole. The stars of which it is formed continually scatter their mass broadcast in the form of radiation. As they do so, their gravitational hold on one another weakens, so that the whole galactic system for ever expands. It must be the same with the other star systems in space. Throughout the universe, all the smaller broken pieces, satellites, planets, stars, are scattering away from one another in apparent opposition to the laws of gravitation.

Still more surprising and sensational is the recent discovery that the largest pieces of the universe—the great extra-galactic nebulæ we have been discussing—are to all appearances engaged in a similar scattering. When proper allowance is made for the rotation of our own system of stars, all, or nearly all, the nebulæ appear to be receding from it, the nearer nebulæ with small speeds, and the more remote nebulæ with greater speeds; in general speed is approximately proportional to distance. This simple law seems to hold to the very farthest of the nebulæ—Hubble finds that for every million light-years of distance there is a speed of recession of about 105 miles a second. The last nebula to be investigated at Mount Wilson shows a speed of recession of 12,300 miles a second (see Fig. 6); its distance, as estimated from its faintness, being about 105 million light-years. On the face of it, this looks as though the whole universe were uniformly expanding, like the surface of a balloon while it is being inflated, with a speed such that it doubles its size every 1400 million years.



Mt. Wilson Observatory.

FIG. 6.—Spectrum of the brightest nebula in the Leo Cluster.

At the top and bottom are the spectrum of an ordinary star. The pair of lines N are the *H* and *K* lines of calcium in their normal position. The middle spectrum is that of the nebula. The pair of lines D are the *H* and *K* lines of calcium displaced to the red by a fifteenth of their wave-length, this corresponding to a speed of more than 12,000 miles a second.

One of the great puzzles of astronomy at the present moment is whether these apparent motions of recession are real or not. The only evidence for them is that the nebular spectra show displacements to the red, which, interpreted in the most obvious way as Doppler effects, give the speeds already mentioned. Yet every spectroscopist knows that many factors besides motions of recession may redden light.

There is one strong theoretical argument in favour of regarding the apparent speeds as real. Einstein's original cosmology supposed the universe to be as full of matter as a universe of its size could possibly be without violating the theory of relativity. Recently, Lemaître of Louvain has shown that a universe of this type would not be static—there would be an unstable quality about it. The condensation of the primeval gas into distinct nebulæ, and the imprisonment of a large part of its free energy in these nebulæ, would cause the whole universe to start expanding, in which case it would continue to expand, its radius finally increasing exponentially with the time, until it ended up as an empty universe—finite matter spread through infinite space. Throughout the motion the relative speed of recession of any two nebulæ would be exactly proportional to their distance apart, so that, at first glance at least, this theory seems exactly to fit the observed facts. It not only provides a suggestion as to why the nebulæ may be receding; it goes much farther and predicts that they must be receding. If Einstein's relativity cosmology is sound, the nebulæ have no alternative—the properties of the space in which they exist compel them to scatter.

Yet the very magnitude of the apparent speeds casts doubt on their reality; they would reduce the whole existence of the universe to a mere flash—at any rate in comparison with what we have recently believed. If they are real, Eddington has calculated that the universe must have started from a radius of about 1200 million light-years, and that its total mass must be about $2{\cdot}3 \times 10^{55}$ gm., which is the mass of $1{\cdot}4 \times 10^{79}$ protons and an equal number of electrons. This amount of matter, spread throughout the initial universe of 1200 million light-years' radius, would give a mean density of $1{\cdot}4 \times 10^{-27}$ gm. per c.c. So far as we can tell from the masses of the extra-galactic nebulæ, the present average density of matter in space appears to be not less than 10^{-30} gm. per c.c., which, with the same amount of matter, would assign a radius of 13,200 million light-years to the universe—only eleven times its initial value. If, then, the motions are real, the universe is only at the beginning of its career; it cannot have doubled many times since it started. As it appears at present to be doubling in size every 1400 million years, the few doublings which these figures permit cannot have occupied more than 10,000 million years at most.

General calculations on the ages of astronomical bodies point to far longer periods of time. Both single stars and binary systems show an approximation to equipartition of energy which must have taken far longer than this for its establishment. If we concede that the universe has expanded to many times its original size, so that the stars were initially far more closely packed than now, the figure originally calculated of a few millions of millions of years may have to be reduced by a good deal, but not, I fear, by enough to remove the conflict of evidence.

In any event a piece of evidence remains which cannot be dismissed in this way. Spectroscopic binaries consist of pairs of stars revolving round one another. Observation reveals a complete sequence; it begins with systems which appear to have just broken into two as the result of rotation—pairs of stars describing circular orbits, and almost in contact—and ends with systems in which the two stars are far apart and describing elliptical orbits. Observation also shows that the stars at the beginning of the sequence are many times more massive than those at the end. It seems likely that those which are now at the end must have begun at the beginning, and lost the greater part of their mass in the form of radiation. To do this would take millions of millions of years, quite regardless of whether the universe was expanding or of what it was doing.

Considerations such as these make it very difficult to believe that the universe can be such an ephemeral concern as the apparent speeds of recession of the nebulæ would suggest.

There is, however, every reason to hope that within a very short time we shall know the truth about this puzzle, and, whatever the solution may be, there seems to be a considerable chance that it may provide us with a clue, perhaps even with a key, to the structure of the universe as a whole. Such a clue—and still more, such a key—would be of the utmost value. Until quite recently the man of science, like most men, accepted the fundamental ingredients of our experience—space, time, matter, and energy—more or less at their face value. The most obvious and superficial interpretation suggested by everyday experience was assumed to correspond fairly closely to ultimate reality. The theory of relativity has shown that we were utterly wrong about space and time, and we are beginning to suspect that we are still just about as far wrong about matter and energy. The concept of an expanding universe may prove after all to be a false scent, and the truth may lie in some other direction, but in either event the observed phenomena must mean something, and their true interpretation, when it is found, may carry us a step on towards the solution of the greatest mysteries of the external world—the nature of space, time, matter, and energy, and of the combination of all these which constitute the physical universe.

Printed in Great Britain by R. & R. CLARK, LIMITED, *Edinburgh.*

the public the results of science in civic as well as in industrial life, and to extend the task of co-ordination so as to assist the growth of co-operation and the emancipation of industry and society from false values and mechanisation of life.

SCIENTIFIC information is disseminated in Germany in several ways. There is the scientific news service "Pallas", edited by Dr. Paul Neuburger, Berlin-Zehlendorf, Cecilienstr. 10. This distributes in very clearly printed typescript a foolscap sheet appearing about every other day. The paragraphs are of general interest and seem suited for immediate use in the daily press of German-speaking countries. The Reichszentrale für wissenschaftliche Berichterstattung Pressestelle, Berlin, N.W.7, Unter den Linden, 38, is another information bureau issuing scientific news. Its items seem suited for immediate use in scientific, technical, and educational journals, and by translation without further condensation they might be utilised in English journals. A good deal of the material is taken from *Forschungen und Fortschritte*, a journal of research and scientific progress appearing three times a month in some twelve pages under the editorship of Dr. E. Kiessling, Berlin, N.W.7, Unter den Linden 38. There are two editions, *Korrespondenzblatt*, printed on one side only of the paper, for 5 marks quarterly, and *Nachrichtenblatt*, printed on both sides, for 3 marks quarterly. The reprinting of signed articles is only permitted with acknowledgment of the source. This journal is written for more scientific and academic readers. The separate authors are specialists intimately concerned with the researches they describe. Special paragraphs are devoted to a diary of coming congresses and reports of international scientific organisations. *Die Naturwissenschaften*, edited by Dr. Arnold Berliner, and published by Verlag Julius Springer, Berlin, W.9, Linkstrasse 23-24, is a weekly journal of science. It is now in its eighteenth year and is the official organ of the German Association of Men of Science and Physicians. *Die Naturwissenschaften* may be particularly commended to those who are trying to acquire some general familiarity with scientific German in various fields. The editor is to be congratulated on having kept this journal alive during the difficulties of the past few years.

SIR ALEXANDER RODGER, chairman of the Department of Forestry, Section K (Botany) of the British Association, gave a short review, on Sept. 25, of the inception and development of forestry in the Empire during the last hundred years. Sir Alexander said that although forestry has, in some European countries, been long regarded as an important part of scientific knowledge, the 'forest sense' and the importance of forestry have only recently begun to come to the fore in Great Britain. With few exceptions, forestry was little understood throughout the Empire before the beginning of the present century. Sir Alexander quoted extracts from various recent forest reports, which showed that, until comparatively recently, the neglect and failure to apply the most elementary principles of forest management have led to direful results. The last twenty to thirty years have seen a realisation of the immense value of the forests of the Empire, depleted as many of them are. Since 1900, and even more since the War, the value of the forests has been continually impressed upon governments by imperial and other conferences. Technical instruction has of recent years made great strides, especially in Great Britain, where forest officers are trained for many parts of the Empire, and forest research in India, Canada, Australia, and Great Britain has attained an importance never before recognised for it. The skilled use of exotics also has turned out to be of the greatest importance in Australia, New Zealand, India, and elsewhere.

IN his Cantor Lectures at the Royal Society of Arts on "Some Recent Developments in Microscopy", Prof. L. C. Martin reviews a number of developments in microscopy, especially those respecting which not much has yet been published, such as ultra-microscopy, the theory of dark-ground illumination and resolving power with it, Gerhardt's interference method, and ultra-violet microscopy (*Jour. Roy. Soc. Arts*, Aug. 21 and 28, 1931, pp. 871 and 887). For the quartz homogeneous system employed for ultra-violet microscopy, it is necessary to use an immersion fluid of refractive index of 1·4961, and a solution of glycerin and water is employed. This mixture is, however, hygroscopic except in the driest atmosphere, and absorption of water vapour alters the refractive index. To obviate this, as cane-sugar solution is also transparent to ultra-violet light, it is suggested that a mixture of the glycerin and cane-sugar solutions of the proper refractive index may be made in such proportions that it neither absorbs water nor evaporates, but remains constant. The proportions would have to be adjusted for varying degrees of atmospheric humidity.

THE new Ramsay Memorial Laboratory of Chemical Engineering at University College, University of London, is to be opened on Nov. 26 by H.R.H. Prince George. The Laboratory is designed to provide a post-graduate training in the principles underlying the design, fabrication, and operation of all kinds of chemical plant. Special features of the building are a large industrial laboratory in which semi-large scale plant can be erected and tested, a well-equipped workshop in which plant units may be fabricated or repaired, a drawing office, and a general experimental laboratory. Special laboratories are devoted to the study of fluid flow, heat transfer, and the examination of fuels. Provision is also made for the original investigation of chemical engineering problems, either on a small or semi-large scale. The building is designed to accommodate fifty post-graduate students. Its erection and equipment have been made possible by the generous contributions of a number of firms of chemical manufacturers and chemical plant manufacturers.

THE new laboratory for physical chemistry in the University of Freiburg im Breisgau was opened on Oct. 30. At the same time honorary degrees were conferred on Lord Rutherford, Prof. Siegbahn, and Prof. Goldschmidt. The old laboratory was one of the first institutes for physical chemistry erected in Germany. The new laboratories are especially well equipped with apparatus for carrying out chemical analysis by X-rays, and extensive facilities are available for investigating the composition of minerals and alloys by chemical, radioactive, and spectroscopical methods. A large section of the laboratories is devoted to the study of diffusion phenomena, especially in alloys.

TEN years ago, on March 29, 1921, John Burroughs died. His writings, full of close observation of wild life, expressed with studied simplicity, have done much to encourage an interest in Nature in America and beyond. The John Burroughs Memorial Association has commemorated the tenth anniversary by the publication of "The Slabsides Book of John Burroughs", and one of the chapters appears in *Natural History* (New York, Sept.–Oct. 1931). It contains personal recollections of the poet-naturalist and of his life at his mountain retreat, the rustic cabin of Slabsides, near Riverby, by Clyde Fisher, whose friendship with Burroughs extended through many years. The article brings out very simply the ideas which governed the poet's life and writings, and the author's photographs add to the intimacy of his theme.

AT a meeting of the Royal Microscopical Society held on Oct. 21, Prof. K. Fujii of Tokyo, Prof. Victor Grégoire of Louvain, and Prof. O. Rosenberg of Stockholm were elected honorary fellows of the Society.

THE Streatfeild Memorial Lecture will be delivered at the Institute of Chemistry on Nov. 20, at eight o'clock, by Dr. J. V. Eyre, who will take as his subject "Recent Advances in the Fermentation Industries".

THE American Association for the Advancement of Science will hold its eighty-ninth meeting at New Orleans on Dec. 28, 1931–Jan. 2, 1932, under the presidency of Prof. Franz Boas, professor of anthropology, Columbia University.

AT the anniversary meeting of the Mineralogical Society, held on Nov. 3, the following officers were elected: *President*, Sir John S. Flett; *Vice-Presidents*, Dr. G. F. Herbert Smith, Prof. C. Gilbert Cullis; *Treasurer*, Mr. F. N. Ashcroft; *General Secretary*, Mr. W. Campbell Smith; *Foreign Secretary*, Prof. A. Hutchinson; *Editor of the Journal*, Dr. L. J. Spencer.

THE following officers have been elected for the Cambridge Philosophical Society for the year 1931–32: *President*, Prof. A. Hutchinson; *Vice-Presidents*, Mr. G. Udny Yule, Dr. W. H. Mills, Mr. F. T. Brookes; *Treasurer*, Mr. F. A. Potts; *Secretaries*, Mr. F. P. White, Dr. J. D. Cockcroft, Dr. H. Hamshaw Thomas; *New Members of the Council*, Dr. R. H. Rastall, Mr. C. F. A. Pantin, Mr. N. F. Mott.

THE following appointments have recently been made by the Secretary of State for the Colonies: Mr. C. E. J. Biggs, agricultural officer, Uganda, to be senior agricultural officer, Uganda; Mr. W. J. Badcock, to be agricultural officer, Uganda; Mr. G. D. P. Olds, to be agricultural field officer, Malaya. The following assistant conservators of forests have been appointed: Mr. F. G. Harper and Mr. F. J. Lyon (Gold Coast); Mr. C. V. Wallace (Sierra Leone); Mr. D. G. B. Leakey (Kenya); Mr. R. G. Miller (Northern Rhodesia); Mr. F. H. Landon (Malaya).

AT a general meeting of the Société française des Électriciens on Nov. 7, it was decided to confer the title of honorary member on Mr. Percy F. Rowell, secretary of the Institution of Electrical Engineers, in recognition of his work in establishing close collaboration between the French society and the Institution of Electrical Engineers, particularly during the Anglo-French Congress held in Paris in 1913, the meeting of the Institution held in France in 1929, and the Faraday celebrations held in London in 1931.

IT is announced by Science Service, Washington, D.C., that Prof. Theodore Lyman, emeritus professor of physics in Harvard University, has been awarded the Frederick Ives Medal of the Optical Society of America for his pioneer work on the ultra-violet spectrum of hydrogen gas. Prof. Lyman's name is commemorated in the 'Lyman series' of the hydrogen spectrum, which, with the series detected by Balmer and by Paschen, are of fundamental importance in modern views of the energy levels within the atom.

THE council of the Institution of Civil Engineers has awarded the Indian Premium for the session 1930–31 to Mr. G. C. Minnitt (Bombay). It has also made the following awards for the session 1930–31 in respect of selected engineering papers, published without discussion: A Telford Gold Medal to Mr. Herbert Addison (Giza, Egypt), and Telford Premiums to Mr. H. A. Sieveking (London), Dr. William Blackadder (Aberdeen), Mr. R. F. Legget (Montreal), and jointly to Messrs. R. G. C. Batson and H. R. Mills (Teddington). In respect of papers read at students' meetings in London, or by students before meetings of local associations, during the same session, the following awards have been made: The James Forrest Medal and a Miller Prize to Mr. I. W. G. Freeman (London), and Miller Prizes to Messrs. V. A. C. Durand (Cardiff), F. C. Ball (London), T. A. Burnside (Glasgow), F. R. Paynter (Newcastle-on-Tyne), D. H. McPherson (Glasgow), S. G. Barrett (Manchester), E. H. Ely (London), and H. E. Orr (Yorkshire).

MESSRS. Wheldon and Wesley, Ltd., 2 Arthur Street, W.C.2, have just issued a 'clearance' list of nearly 1000 second-hand books on geology, meteorology, mathematics, astronomy, chemistry, and physics. The prices asked are very reasonable.

THE Cambridge University Press announces for early publication Vol. 4 ("Meteorological Calculus: Pressure and Wind") of Sir Napier Shaw's "Manual of Meteorology". The work will contain a summary of contents and an index to the four volumes. The same house also gives notice of "Partial Differential Equations of Mathematical Physics", by Dr. H. Bateman, and "Cartesian Tensors", by Dr. Harold Jeffreys.

Letters to the Editor.

Viscosity of Liquids.

I WAS extremely interested to read, in NATURE for Oct. 24, Prof. G. W. Stewart's letter, in which he states that his X-ray diffraction experiments strongly support my theory of viscosity, and I look forward with eagerness to reading the full account of his results. We are both in agreement that the liquid state is more akin to the crystalline than to the gaseous state, and it is in this connexion that I wish to direct attention to another result of my theory which bears on this point, more especially as fuller publication has, by various mischances, been delayed.

I postulate that liquid viscosity is due to an interchange of momentum between adjacent layers, effected not, as in a gas, by a passage of molecules from one layer to the other, but by a temporary union of molecules, which does not endure for longer than the very brief time required for the molecule to acquire a common velocity of translation—a temporary holding of hands between individuals of two parallel rows moving past one another rather than a stepping bodily from one row to the other. The nature of the union need not be discussed here; all that is demanded of it is that it should produce momentarily a common velocity of the molecules. This leads to the expression

$$\eta = \frac{2m\nu}{\sigma}$$

where m is the mass of a molecule, σ the average distance between the centres of molecules, and ν the frequency of junction per second, which is also, of course, the frequency of disjunction, since the union is of negligible duration. The variation of ν with temperature is an essential feature of the theory, but I am not at the moment concerned with that, but rather with the value of ν at the melting point of the liquid.

Suppose that we make the assumption, which may appear startling, that when a solid is melted it still retains in the liquid form sufficient of its crystalline character for the molecules to possess a frequency of vibration which is practically the same as that of the solid form at the melting point. This is not so remote from Lindemann's theory, in which he derives the frequency of vibration of the solid state of elementary substances at the melting-point from the assumption that melting takes place when the amplitude of the atomic vibration becomes about equal to the average distance apart of the atoms. There is fairly good agreement between the values derived from other methods and those found from Lindemann's formula, which is

$$\nu = C\sqrt{\frac{T_m}{A V_A{}^{2/3}}}$$

where T_m is the melting point, A the atomic weight, and V_A the volume of a gram-atom at temperature T_m. Suppose that we substitute the frequency ν so found in the viscosity formula. Since $\sigma = \left(\frac{V_A}{N}\right)^{1/3}$, and $m = \frac{A}{N}$, where N is Avogadro's number, we obtain for the viscosity η_m at the melting point

$$\eta_m = 2C\frac{(AT_m)^{1/2}}{(NV_A)^{2/3}}.$$

Lindemann gives for the constant C the value $2 \cdot 8 \times 10^{12}$. Substituting this, and the value $6 \cdot 06 \times 10^{23}$ for N, we have

$$\eta_m = 7 \cdot 82 \times 10^{-4}\frac{(AT_m)^{1/2}}{V_A{}^{2/3}}. \quad . \quad . \quad (1)$$

The following table shows the calculated and experimental results for elementary substances, of which the viscosity of the liquid form in the neighbourhood of the melting point can be found from published experimental data. For many liquid metals the viscosities, as found by different workers, show such large discrepancies that they have not been used.

Element.	Melting Point.	Viscosity of Liquid in the Neighbourhood of the Melting Point.	
		Calculated.	Experimental.
Mercury .	234·2° Abs.	0·0283	0·021
Bromine .	265·7	0·0132	0·0147
Iodine .	386	0·0198	0·0235
Chlorine .	171	0·0104	0·0143
Oxygen .	54	0·0038	$>$0·0019
Hydrogen .	14	0·00051	$>$0·00013

As regards the viscosities of liquid oxygen and hydrogen, only one determination, that of J. E. Verschaffelt, exists, namely, at 90° abs. for oxygen ($\eta = 0 \cdot 0019$), and at 21° abs. for hydrogen ($\eta = 0 \cdot 00013$), temperatures which are respectively 67 per cent and 50 per cent above the melting point. It is certain that the viscosities at the melting point must be considerably higher than those shown in the table.

It should be emphasised that the constant in formula (1) is not arbitrary, but taken from Lindemann's formula. When this is remembered the agreement between experiment and calculation must be considered as very satisfactory, and furnishing a strong confirmation of the conception of the liquid state put forward, namely, that liquids at the melting point behave as crystals which have, so to speak, lost their general rigidity, while retaining local memory of their former state. I have sketched the argument leading to formula (1) as briefly as possible: I hope to make it a little more convincing when I have more space at my disposal.

Anomalous Variation of the Electrical Conductivity of Quartz with Temperature at the Transformation Point.

FOR many years the variation of electrical conductivity of crystalline dielectrics with temperature has been studied by different physicists; for example, A. Joffé [1] has studied this problem with quartz, calcite, ammonium-alum, and copper sulphate, and found that their conductivity σ is expressed by $\log \sigma = \frac{A}{T} + B$, where T is the absolute temperature, A, B the material constants. More recently, W. Seith [2] has also studied this problem with lead chloride and iodide crystals and deduced the expressions $\sigma = Ae^{-Q/RP}$ for the chloride, and $\sigma = A_1e^{-Q_1/RP} + A_2e^{-Q_2/RP}$ for the iodide, where A, A_1, A_2 and Q, Q_1, Q_2 are material constants, T the absolute temperature, and R the gas constant. But no one has noticed that there exists any anomalous change of the electrical conductivity of quartz at the temperature 573° C.

It is well known that the index of refraction, specific heat, Young's modulus, and other physical properties of quartz, except its electrical conductivity, show anomalous changes at its $\alpha \rightleftarrows \beta$ transformation.

According to the investigation by X-ray analysis on the structure of α and β quartz given by W. Bragg and R. E. Gibbs,[3] the projective area of a triangle formed by silicon atoms on the plane perpendicular to the principal axis becomes smaller by its rotation at the transformation $\beta \longrightarrow \alpha$. Thus, it might be expected that the electrical conductivity of quartz would increase considerably at the $\alpha \longrightarrow \beta$ transformation. We measured the change of electrical conductivity of quartz with temperature with special precautions and accuracy, especially in the temperature range about 500°–650° C.

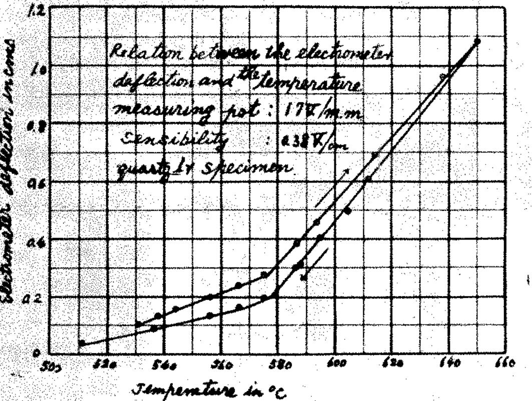

FIG. 1.

We used two different methods in our experiments. In one, we measured the voltage drop with time produced by a standard resistance connected with the specimen and the earth in series (the stationary value of the voltage drop will be proportional to the electrical conductivity of the specimen); and in the other, we measured the accumulation of charge on the specimen with time, and the conductivity is calculated by the ratio of the initial current (the initial tangent of the accumulating curve) to the applied voltage. Some of our results are given herewith.

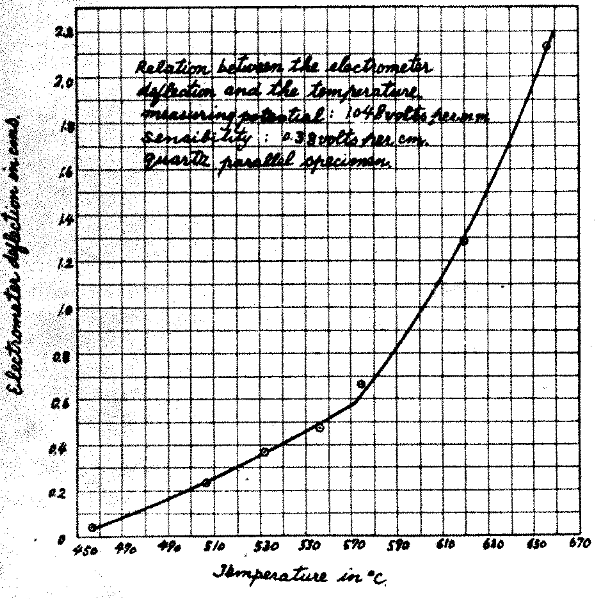

FIG. 2.

Fig. 1 shows the variation of the electrometer deflection due to the voltage drop of the standard resistance of 800,000 ohms with temperature for a quartz plate cut perpendicular to its optical axis. The ordinate is proportional to the electrical conductivity of the quartz. The arrows in this diagram show the results for heating and cooling, and the time intervals for heating and cooling are nearly the same and equal to about fifteen hours. Thus, the electrical conductivity of quartz varies anomalously at the $\alpha \rightleftarrows \beta$ transformation temperature 573° C. Fig. 2 shows a similar result for quartz plate cut parallel to its optical axis. In this case also the anomalous change of the electrical conductivity occurs at the transformation temperature 573° C. Fig. 3 shows the result by the accumulation charge method with the parallel quartz plate. In this case the conductivity increases discontinuously at the temperature 573° C.

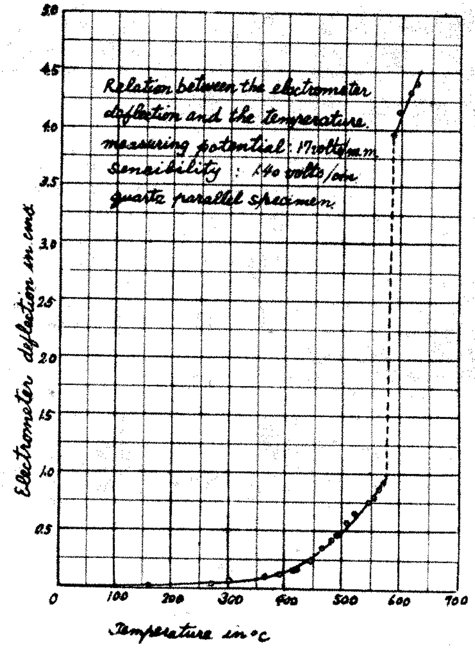

FIG. 3.

There is considerable difference between the results given in Figs. 2 and 3 on the variation of the electrical conductivity at the transformation point, but this is an apparent difference only, because, in Fig. 2, the stationary value of the conductivity is taken and in Fig. 3 the initial value of it is considered. We have already shown that the electrical conductivity of dielectrics is of two kinds, namely, true and apparent, and the latter decreases with time and tends to the stationary value.[4] It is the apparent conductivity which is measured in the experiments above on quartz.

Hence we conclude that the electrical conductivity of quartz increases with temperature, and at its transformation point, 573° C., it shows an anomalous variation similar to that of the other several physical constants of quartz.

Control of Prickly-Pear by the Cochineal Insect.

I HAVE read with interest the communications of Messrs. C. T. Jacob [1] and W. B. Alexander [2] on this subject. Referring to the introduction of the cochineal insect into India, the latter remarks: "In India, the offer was considered at a conference of the entomologists of the various provinces, and it was decided not to accept it, on the ground that prickly-pear was largely used for hedges, and that, where it threatened to become a pest, it could easily be eradicated, as abundant cheap labour was available". I am constrained to state that neither the first part nor the latter portion of this statement describes the real facts. I may state that, though the Government was not very enthusiastic about the introduction of this new insect, it never had any conference of provincial entomologists or gave any such opinion regarding the necessity for, or the easy method of, eradicating prickly-pear when needed. In South India the prickly-pear has been felt to be a very serious pest and nuisance for years, and the Government has been spending a great deal of money in getting the same eradicated in various ways without any appreciable success until now. Nor has it ever been felt by any responsible person that "it could easily be eradicated, as abundant cheap labour was available".

Anyone travelling, even along the railway tracts of South India, can easily form an idea of the extensive areas of valuable arable and pasture lands overrun by this terrible pest. It is not only harmful in harbouring dangerous reptiles, etc., as Mr. Jacob puts it, but also is in every way an undesirable weed. Among other things, it blocks up village footpaths, covers the banks and foreshores of streams and rivers, encroaches badly and quickly on cultivated areas, and in fact makes the whole country-side very unsightly. The introduction of this cochineal, though through a private agency, was certainly not a "thoughtless importation" of a strange animal; on the other hand, it is being felt as a real boon. By its steady and effective work of controlling the weed (*O. dillenii*) the insect has not only helped in the saving of thousands of rupees usually spent year after year to keep the same under some control, but it has also been clearing the country-side remarkably and very satisfactorily.

Control of Humidity of Air Currents.

PROF. J. B. SETH [1] has described a method of obtaining air currents of which the humidity can be regulated. I do not doubt that his method is a good one, though I have no experience of it. But may I point out that humidifying the air by mixtures of sulphuric acid and water is also a good method, provided that certain precautions are taken. It is perhaps unsuitable if large volumes of air are required. The air should be blown, not sucked, so that any leaks which may occur will be outwards. The air should not be bubbled through the acid, for that imparts to it an acid spray, which is most difficult to remove; it should pass through several Woulfe's flasks, containing pumice well wetted with the acid. Nearly all the humidifying (or drying) of the air takes place in the first Woulfe's flask, to which the gradual alteration in the strength of the acid is almost confined. After the last Woulfe's flask, arrangements should be made for drawing off a sample of the air stream; it may be bubbled through an indicator to show that it is free of acid; or it may go past a dew-point apparatus, enclosed in glass. This is most important, as it provides a method of hygrometry, perhaps the most suitable for this particular purpose. I have recently figured a convenient dew-point instrument.[2]

[1] NATURE, Oct. 10, p. 638.
[2] *Bull. Entom. Res.*, vol. 22, p. 431.

WE have read with interest the communication of Prof. J. B. Seth in a recent issue of NATURE [1] on a method of obtaining air currents of various relative humidities. The method described by Prof. Seth makes use of the principle of admixing appropriate proportions of desiccated and saturated air; it appears to be assumed, however, that saturation may be effected by bubbling air through a bottle full of water. In a recently published paper [2] we have shown that this assumption, which is very commonly made, is not justified. Passage of air at a rate of approximately 60 c.c. per min. through a Dreschel wash-bottle full of water produced a relative humidity of only 80 per cent; whereas at the same and much higher rates of flow complete saturation was obtained by admitting steam into the air current and condensing out the excess moisture under thermostat conditions. Lower relative humidities were obtained quantitatively by suitably admixing saturated and desiccated air.

Since the failure of the 'bubbling method' is undoubtedly attributable to factors connected with hydrostatic pressure, clearly it cannot be overcome merely by increasing either the number of bottles or the depth of liquid. The point to which we desire especially to direct attention is the doubt that must be associated with any method of saturating a stream of air that depends on its passage vertically through a column of water.

Short Wave Reception and Ultra-Radiation.

A FEW years ago W. Kolhörster [1] referred to the possible connexion between short wave fading and the fluctuations of ultra-radiation, and suggested comparative investigations. Up to now such investigations have not been undertaken, so that still nothing is known concerning this.

In the following I wish to direct attention to an undoubted analogy in the changes in short wave reception and in the changes in intensity of ultra-radiation during terrestrial magnetic disturbances. This permits conclusions to be drawn as to a connexion between the two phenomena.

The auditory reception strength for short wave long-distance reception increases gradually for a few days before a magnetic disturbance, until, on the day of the disturbance, it decreases suddenly, even to inaudibility. It first increases again in the course of the following days, there being a slow increase but for superimposed fading effects.[2] Corlin [3] has now been able to derive statistically a completely inverse picture from his ultra-radiation observations in northern Sweden in the winter of 1929–30. According to this, the strength of the radiation decreases slowly and continuously for some time before a disturbance, jumps strongly upwards at the beginning of the disturbance (the impetus stage), and then slowly becomes less again during the further course of the disturbance (the main oscillation stage) and its after-effects. This agreement must be more than accidental, and permits the conclusion, made with all due reservation, that increase of ionising ultra-radiation makes reception conditions worse, and conversely. The known deterioration of reception during the daylight hours, when there is an increase in ionisation in the upper layers of the atmosphere due to the ultra-violet radiation from the sun, also affords evidence for this inverse proportionality between reception strength and ionising radiation. W. M. H. SCHULZE.

Rhythmic Breaking of Ship-waves.

ON a recent voyage from Australia, I observed a phenomenon in connexion with ship-waves to which no reference is made in the literature on waves with which I am acquainted. Dr. Vaughan Cornish's book on "Waves of the Sea", etc., makes no mention of it.

The diverging waves produced by the motion of the ship increase in height and steepness on the near-side as they move outwards from the ship and then break towards the ship. The fact to which I wish to direct attention is that this breaking is, under favourable conditions, regularly periodic.

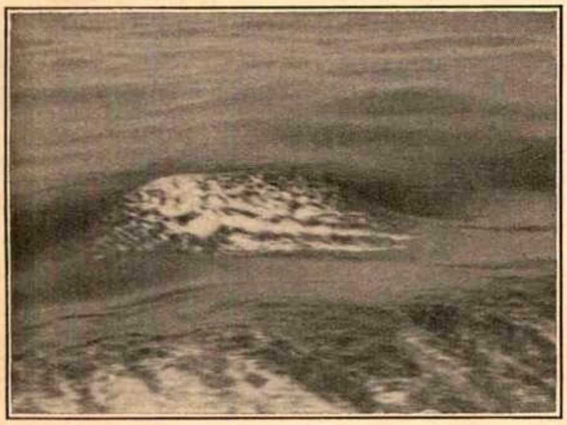

FIG. 1.

Prof. Hartung of Melbourne, who was a fellow-passenger, was kind enough to take some photographs of this effect (Fig. 1). Two parallel bands of foam are very definitely shown, a third not quite so definitely. Occasionally as many as half a dozen such parallel breaks in the wave-crest could be seen, though more frequently these are broken by transverse bands of turbulence. KERR GRANT.

Constitution of the White Dwarf Stars.

IT is generally held that the white dwarf is in the degenerate state in the sense of the statistics of Fermi and Dirac. This assumption leads to another consequence bearing on the relative abundance of elements in the same star. Assuming further that (i) all atoms of various elements in the white dwarf are stripped of their extranuclear electrons, and (ii) all kinds of nuclei of atoms are formed entirely from protons and electrons, the thermo-equilibrium among them is determined from Milne's equations.[1] The simplified form is

$$\frac{1}{m_E}\left(\frac{c_E}{q_E}\right)^{\frac{2}{3}}=\frac{\mu}{m_P}\left(\frac{c_P}{q_P}\right)^{\frac{2}{3}}+\frac{\nu}{m_e}\left(\frac{c_e}{q_e}\right)^{\frac{2}{3}}+\frac{2}{h^2}\left(\frac{4\pi}{3}\right)^{\frac{2}{3}}U \quad . \quad (1)$$

with the equation of nuclear formation of an element E from μ protons (P) and ν electrons (e),

$$\mu P+\nu e \rightleftarrows E+U,$$

where m, c, and U denote respectively the mass of an atom, the concentration and the heat of formation. μ and ν are expressed by Z (the atomic number), and the mass of an atom as follows:

$$\mu=\frac{m_E}{m_P}, \quad \nu=\frac{m_E}{m_P}-Z_E. \quad . \quad . \quad (2)$$

Usually the first term of the right-hand side of (1) is negligibly small.

U is calculated from the mass-defect, with the result that U increases monotonically with the mass number of the element. As all terms of the right-hand side of (1) are positive, it is quite clear that the nuclear concentration of an element increases with its atomic weight (almost proportional to its square). Therefore it may be concluded that the heavy radio-elements exist abundantly in the white dwarfs.

Dehydration of Salts.

IN the course of some investigations it was found advantageous to have a uniform and general method of dehydration. Such a method was found in the extension of the drying process applied originally to 2-nitro-*p*-cresol.[1] In general, dehydration was carried out by distilling a neutral liquid of high vapour tension containing the hydrated salt or its aqueous solution.

As an example, crystals of copper sulphate were placed in toluol and the latter distilled off until no further water could be detected in the distillate. The anhydrous copper sulphate so obtained, though lacking in cohesion, frequently retained its original crystalline form. Dried over solid paraffin in a desiccator, the copper sulphate was found as whitish fragile crystals free from water.

In a similar manner the dehydration of magnesium chloride and various salts of iron, nickel, and cobalt was carried out. This method practically eliminates decomposition of the product and side reactions, such as oxidation and reduction. Owing to its elasticity as regards medium, temperature, and pressure, the process may be of general application.

An attempt to extend Stephen's acetic anhydride dehydration of stannous chloride[2] to other salts met with but partial success.

Although dehydration was in most cases achieved, (1) the process was limited to solids in a finely divided condition; (2) in most cases the reaction was sluggish and required heating; (3) the dehydrated salts were found to retain tenaciously some acetic acid and its anhydride, a feature apparently general in the case of salt-acid mixtures.

Research Items.

Prehistory of West Africa.—In *Africa*, vol. 4, no. 4, M. P. Laforgue reviews the present state of our knowledge of the stone age in West Africa. Both the major divisions of stone age culture are represented with a distinct but ill-defined period of transition, revealed by a large number of 'Tardenoisian' implements. The African palæolithic peoples, like the Eurasian, lived in caves, rock-shelters, and in the forests, where they were succeeded by the neolithic peoples, as is shown by superimposed deposits. Three zones of prehistoric culture can be distinguished in strongly marked local developments of a basal culture: (1) a Saharan zone north of 18° N.; (2) a Sahelian zone between 18° and 14° N.; (3) a Soudanese zone between 14° and 4° N. The Saharan zone is distinguished by the use of flint and limestone. Weapons predominate, and the implements attain great perfection of form and technique. They point to a northern and eastern origin, and have been attributed to nomad hunting tribes. Pottery is rare and implements of agriculture non-existent. It is in this zone that the greater number of palæolithic sites are found, Mousterian industries predominating. (2) The Sahelian sites show a predominance of tools and the implements of agriculture. All kinds of stone are employed; arrow- and lance-points are found, but without the refinement of those of the Saharan zone. The industry as a whole is agricultural. Pottery is abundant; it is ornamented by the use of the tips of the fingers. (3) In the Soudanese zone, limestone is generally in use, the implements being axes, hammer-stones, grinding-stones, and numerous flakes of limestone and basalt, of which it is not possible to determine the use. Evidence from this part of Africa, especially in the forested area, is scant.

Indian Place-Names.—In the *Indian Antiquary* for October, Rai Bahadur Hira Lal discusses the origin of the place-names of the Central Provinces. During the times of Srî Râmacandra a great part of what is now the Central Provinces was, according to recent interpretation, Daṇḍakâranya or Daṇḍaka forest. The forest was inhabited by wild tribes, among whom the Gonds were prominent, as they are still. It is likely, therefore, that the place-names were in the language of the aboriginal tribes, especially of the Gonds and Oraons, though many of them have undoubtedly been Aryanised. Relics of tha Sabars' or Śavaras' language have been pointed out, for example, in Janasthâna from *jaitan*, 'below', or Daṇḍaka, 'full of water'. The following are examples of aboriginal names of Gondi origin which have undergone scarcely any change:—A large number of names derived from trees, for example, 'Barelî' from 'barelî', 'banyan' (*Ficus bengalensis*); 'Markâḍîh' from 'markâ', mango. In the single district of Jubbulpur alone there are more than fifty villages named 'Pipariâ' from 'pîpar' (*Ficus religiosa*). The Aryan names carry a suffix, for example, 'Belgâon' from 'bel', a tree, and 'gâon', a village. Certain names are derived from wild animals, birds, insects, etc., as applied to places to which they resorted; 'Malpârâ' from 'mal', a peacock, 'Koṇḍigâon', from 'Koṇḍâ', a bullock. Similar names are common in Aryan nomenclature; for example, 'Bâghpur' from 'bâgh', a tiger, 'Hâthîgadh' from 'hâthî', the elephant. Trees and animal names are joined with words signifying water; for example, 'Aunrâbândhâ', from 'aunrâ', a tree, and 'bândh', embankment, 'Bâghḍabri', tiger-pool. Examples of reptiles and birds are Nagpur, 'Cobra city', Kavâkhâpâ, 'Crow hamlet'. Onomatopœic names imitate the sound of running water or the cry of birds heard in the vicinity, such as Daldali, Murmur, Luṭluṭâ, Rigrigâ, Tuturiyâ.

False Killer Whale in Ceylon Waters.—The stranding of a large school of killer whales, *Pseudorca crassidens*, containing 167 individuals, upon the shores of Velanai in Ceylon, has already been mentioned in NATURE, and now Dr. Joseph Pearson describes the occurrence in more detail (*Spolia Zeylanica*, vol. 16, p. 199, Aug. 1931). Unfortunately the carcases were much decomposed before they were examined at the place of stranding, but one complete skeleton and twelve skulls were preserved for the Colombo Museum, and of these Dr. Pearson records the dimensions. He tentatively suggests that the occurrence of the species, which he regards as a cold-water form, in tropical seas may possibly be connected with a seasonal migration during the breeding season, in order that the young may be born under less rigorous conditions than those of higher latitudes. He cites the fact that the Ceylon school contained many pregnant females and appeared in August, a winter month in Antarctic seas. But our recollection is that the large Dornoch Firth school of October 1927, to which the author makes no reference, also contained pregnant females. It would appear that the three appearances off Ceylon and Southern India, and the rare appearances in the North Sea (two, however, of schools containing a hundred individuals or more), are indications of casual wanderings, occasionally in mass, of a species the headquarters of which may be in sub-Antarctic oceanic waters.

A Virus Disease of Roses in Australia.—A rose disease, known in Australia as 'rose wilt' and 'die back', began to become prevalent during 1908–1912, reached serious proportions in Victoria by 1915, and an alarming increase in the number of plants affected was observed in 1928. This disease, which is restricted to Australia and New Zealand, generally appears in epidemic form, causing great damage in a season, then seems to lose its virulence for some seasons, when it suddenly appears again. The first sign is a curiously recurved appearance of the leaves on young shoots. Defoliation then occurs, commencing at the tips of the shoots and progressing downwards, the 'rose wilt' stage, followed by discoloration and death of the stem, and this 'die back' condition may extend into the older wood. Prescott, Rossi, and others noted the presence of a bacterium in the diseased parts and assumed the disease to be caused by this organism. B. J. Grieve, investigating the disease on behalf of the National Rose Society of Australia (*Australian Jour. Exper. Biol. and Med. Sci.*, vol. 8, pt. 2, 1931, p. 107), finds, however, that in the early wilt stage organisms cannot be detected in the diseased tissues; these appear only in the late 'die back' stage and are probably adventitious. It was proved that both the unfiltered and the filtered juice from diseased plants produced the disease in healthy plants inoculated with it, thus demonstrating that the disease is an infective one and is caused by a filterable virus. A Seitz filter which did not permit a small bacterium to pass was employed. Experiments to test if the rose aphis is a vector yielded inconclusive results.

Tree Growth and Weather.—Having devised a special recording apparatus for the purpose, Hirokichi Nakashima gives very full figures for growth in length for the tree *Pinus nigra* Arnold, var. *austriaca* Hoss, in Japan, in the *Journal of the Faculty of Agriculture*, Hokkaido Imperial University, vol. 22, part 2. Growth is most vigorous from the end of May until the middle of July, and only during a relatively short period is an increase in height of the tree to be noticed. By July 19, 90 per cent of the extension growth had taken place. Increase in height is most marked in the evening; in the morning, just after sunrise, the increase is nil, or there is even a slight decrease in height. During the period of vigorous growth, evaporation has the most definite effect upon growth: on a sunny day, the morning cessation of growth is followed by more vigorous growth in the evening; but on a cloudy day, both fall in growth rate and subsequent increases in length are less marked. In the period that follows, when but a little extension takes place, the most significant factor seems to be the wind, a surprising effect being noted of windy weather which results, on the whole, in a greater increase in length.

Radium in Hawaiian Lavas.—Continuing his work on the radium content of rocks, C. S. Piggot has investigated thirteen samples of lavas from various islands of the Hawaiian group (*Am. Jour. Sci.*, July, 1931, pp. 1-8). The average amount determined is $0{\cdot}96 \times 10^{-12}$ gm. of radium per gm. of rock, the range being from 0·75 to 1·47. The rocks examined are basaltic, with one exception, the latter being a trachyte which gave 0·94, very near to the mean value for the series. Five of the samples were selected to represent various flows of different ages from Kilauea crater; all show practically the same radium content. four being 0·94 and the other 0·90. Poole and Joly in 1924 recorded 0·96 for a ropy lava from Kilauea. Piggot points out that the radium content of Hawaiian basalts is not very different from that determined for sixteen samples of granite from the eastern seaboard of North America from Georgia to Greenland (0·90). The average contents hitherto found for granite rocks range from 0·55 for Antarctica to 6·00 for the Aar Massif, so Piggot's result for granites need not be considered abnormal, though it is unusually low.

Cooling Effects of Ice on the Oceans.—The degree to which ice has an effect in reducing the temperature of the waters of the North Atlantic Ocean was one of the subjects investigated by the United States Expedition in the *Marion* to Davis Strait and Baffin Bay in 1928. In a comprehensive account of Arctic ice in Part 3 of the results of this expedition (United States Treasury Dept., *Coast Guard Bulletin* No. 19), Mr. E. H. Smith points out that glacial ice, which is only two per cent of the ice brought south by the Labrador current, melts mainly in coastal waters, and so cools oceanic waters only indirectly by the mixing of the two waters. The extent of this mixing, considering the ocean generally, is small. Further, he shows that in the area of the Atlantic invaded by pack ice the annual melting counteracts the solar warming of an 80-ft. surface layer by 6° F. Taking the limit to which solar warmth can penetrate as 480 feet, Mr. Smith concludes that melting pack ice opposes the warming of these 480 surface feet by only 1° F. The mean temperature rise by solar heating of the same thickness of surface water is calculated from observations to be 2·1° F. Thus the chilling of the North Atlantic by ice melting is about one-half of the warming during the summer. This was found to be only 10 per cent of the total cooling-effect resulting from the cold waters of the Labrador current. Since the relative proportions of ice and water are the same in the East Greenland current, it may be assumed that this figure of 10 per cent applies to the entire North Atlantic. These results support previous suggestions of Dr. G. Schott and Comdr. Campbell-Hepworth that the agency chilling the North Atlantic is not melting ice but cold water.

Determination of the Yard in Wave-lengths of Light.—Dr. A. E. H. Tutton has published the results of a direct evaluation of the yard in terms of the primary standard of length, the wave-length of the red cadmium line (*Phil. Trans.*, A, vol. 230, pp. 293-322). The determination was actually based upon the yellow neon line, but since the absolute wave-length of this is accurately known, the results may be readily reduced to the basis of the cadmium line. The baseline directly measured in wave-lengths was considerably longer than in any previous determination; the counting of more than five thousand fringes in a continuous sequence is a feat calling for a remarkable degree of visual endurance, and in fact was only achieved as the result of prolonged familiarity and practice. The micrometric comparisons involved in relating this baseline (1/16 in.) to the standard yard were greatly facilitated by the use of fiducial marks ruled by the late Prof. Grayson with almost superhuman skill. Their width was extraordinarily small—half a wave-length, as against fifteen in the case of the standard yard and metre—and they were spaced with even more extraordinary accuracy, of the order of one hundred-thousandth of an inch. Incidentally they dispose very effectually, as Dr. Tutton remarks, of the rather prevalent belief that objects smaller than one wave-length are necessarily invisible. A complete set of measurements was also made, using the red hydrogen line *Hα*. Dr. Tutton's final conclusion is that the yard contains 1,420,210 wave-lengths of red cadmium light.

Cathode Phenomena in the Glow Discharge.—Two papers by Prof. A. Güntherschulze and F. Keller, in the issue of the *Zeitschrift für Physik* for Aug. 15, contain much new information about the phenomena at the immediate surface of the cathode in the glow discharge between cold electrodes. This is a subject which has been little investigated, partly because of its difficulty, and partly perhaps because attention has been concentrated recently on other discharge forms of commercial importance. It has been found that the phenomenon of the primary dark space—the thin dark layer on the surface of the cathode, *within* the cathode dark space—is much more general than had been supposed, it being reported that this is present in discharges through oxygen and nitrogen, where it could not be detected by Dr. F. W. Aston and more recent investigators. It is found that the primary dark space disappears when the cathode fall in potential is raised to about a thousand volts, and it is suggested that this is because the positive ions proceeding towards the cathode then attain for the first time sufficient energy to excite the gas. Simultaneously, with a cathode of magnesium alloy in helium, a new cushion of green magnesium light appears on the cathode surface, and this in turn is separated from the electrode by a minute dark layer. It may prove possible to study cathodic sputtering very directly by this new method, the intensity of the green light being taken as a measure of the amount of magnesium vapour present in the neighbourhood.

Organic Compounds of Gold.—Gibson and Colles, in the *Journal of the Chemical Society* for September, describe the preparation of some co-ordination compounds of gold tribromide with substances such as pyridine, quinoline, and isoquinoline. They state that they have been unable to prepare some of the substances described by Kharasch and Isbell (Nature, Sept. 5, p. 415). The substance previously used in such work and considered to be gold tribromide is shown to be hydrated bromoauric acid, probably $HAuBr_4$, $3H_2O$. The methods of preparation of this substance and of pure gold tribromide, which is almost insoluble in ether and is regarded as $(AuBr_3)_2$ with the gold having a co-ordination number of 4 and not truly tervalent, are described in detail. Although the new co-ordination compounds were expected to be soluble in ether and hence suitable for use with the Grignard reagent, they were generally sparingly soluble, although the Grignard reaction could be carried out and diethyl gold bromide obtained. The yield was, however, smaller than with methods previously developed.

Low Temperature Carbonisation Test.—There exists a scheme of the Department of Scientific and Industrial Research whereby the staff of the Fuel Research Board tests, at public expense, processes for the carbonisation of coal at low temperatures. In accordance with the scheme a plant of the Leicestershire (L. and N.) Coal Distillation Co., at Ashby de la Zouche, has been tested and the report recently issued (London: H.M. Stationery Office, 9*d.* net). In this process the coal is carbonised in a revolving retort heated internally by products of combustion diluted with the gas leaving the retort. The coke product is quenched with water, whereby it is divided into two fractions, one which floats and one which, owing to a high ash content, sinks. The floating portion is briquetted with pitch and, if desired, recarbonised. The yield of clean fuel was 7·4 cwt. per ton of coal, and of tar 14 gallons per ton of coal. The gas is too poor to be of use. Although the yields of products are low, it is pointed out that the raw coal is practically unsaleable, and the product, owing to the character of the coal, makes an excellent fuel for open grates. It is, however, a process only applicable to the poorly caking coals such as occur in the Midlands.

Astronomical Topics.

New Comet.—Mr. J. W. Durrad, of Leicester, has announced the discovery on Nov. 5 of a new comet, visible to the naked eye. On Nov. 9 it was near σ Ursæ Majoris and moving about 4° a day south preceding.

The Leonid Meteors.—Although the rich shower of Leonids is not due until next year, the experience of 1898, combined with the tolerably rich display last year, gives ground for expecting something in the present year. The Computing Section of the British Astronomical Association has been working on the orbit of Tempel's Comet for the last two years. The date assigned as the most probable one for the comet's perihelion is Nov. 1, 1932. If this is near the truth, the comet will make a fairly close approach to the earth about mid-November. Its orbit, according to the calculations, is half a million miles nearer to the earth than it was in 1899, so there are good grounds for hoping that the disappointment of November 1899 will not be repeated.

The most probable date is the night between Nov. 16 and 17. Last year the maximum was about the end of Nov. 16 or early on Nov. 17. Neglecting the effect of perturbations (which have not been calculated for meteors so far from the parent comet), we should expect them to be six hours later this year, owing to the odd quarter day in the year. Hence the richest part of the shower may not come until after dawn on Nov. 17. But watch should be kept through that night, also on the preceding and following nights, as there are some stray members detached from the main stream. The radiant (in the sickle of Leo) does not rise until about 11 P.M., so the watch need not begin until then. Jupiter will be some 10° to the right of the radiant, and will form a convenient guide to it.

Motion of the Perihelion of Mercury.—The point that first attracted astronomical attention to Einstein's general theory of relativity was the close accord that it brought about between the calculated and observed motion of Mercury's perihelion. The agreement was undesigned, and resulted from the initial assumptions without any manipulation. It is not surprising, however, that the result caused closer examination to be made of the amount of the observed motion. *Mon. Not. Roy. Ast Soc.*, vol. 91, No. 9, contains an article on the subject by Dr. J. K. Fotheringham. He refers to an article by von Gleich in *Astr. Nach.*, vol. 241, which emphasises the need of correcting Le Verrier's value of the motion, in view of the evidence that is now available of changes, both secular and periodic, in the rate of the earth's rotation. This is a matter to which Dr. Fotheringham has given much attention; he has applied the latest values of the accelerations and fluctuations, and re-examined the discussions of the transits of Mercury that were made by Dr. Innes and Prof. de Sitter. His result for the excess of motion of Mercury's perihelion above that given by Newtonian theory is so close to Einstein's value that he feels justified in assuming that the Einstein motion applies also to the earth's perihelion. He then obtains 43·95″ for the observed centennial excess of motion of Mercury's perihelion above the Newtonian value. This is as close to Einstein's theoretical value, 42·9″, as could be expected. Fotheringham expresses indebtedness to von Gleich for having shown the necessity of considering the effect of changes in the earth's rotation.

Calendar Reform.—We have received from C. C. Wylie, secretary of an association in Iowa that is interesting itself in the subject of the reform of the calendar, a summary of the views expressed by various groups in the United States. They are printed under four headings: "Astronomy", "Banks", "Education", "Transport". The second group is practically equally divided for and against revision; the other three have decided majorities for revision, reaching 90 per cent in the third group. All the groups favour the retention of the 12-month division; a recent investigation in England (Nature, Oct. 10, p. 610) had a similar result, so that the suggestion of a 13-month year may be ruled out for the present. The main reason is probably its failure to divide into quarters, but the widespread prejudice against the number 13 may have influenced some voters.

It should be noted that the 13-month division is not the complete novelty that some people imagine. In ancient times, when most nations began their months at the new moon, seven years in nineteen were given a thirteenth month.

Recent Excavations at Vinča.

THE report on the excavations at Vinča in the summer of 1931, which was presented to Section H (Anthropology) of the British Association on Sept. 25, on behalf of Prof. M. Vassitz, fully confirmed previous opinion as to the importance of this site, which is now being excavated through the generous assistance of Sir Charles Hyde. It would seem to be abundantly clear that we now know the place, the time, and even the race of what is, up to the present, the farthest outpost to the north-west of Ægean civilisation. It dates possibly from the end of Early Minoan III, and certainly from the beginning of Middle Minoan I. It flourished until the arrival of the Romans about the year A.D. 6. The knowledge gained from Vinča, in Prof. Vassitz's opinion, poses new problems in pre-history not merely in relation to its immediate neighbourhood, but also in regard to a larger area, the Danube basin. It makes new methods of approach to the history of the Danube basin essential.

In the excavations of 1930 a depth of 8·8 metres was reached on one part of the site. Between the strata containing the earliest house remains which show a rectangular construction (down to 8·6 metres) and the original loess surface is a stratum of black earth about 7 metres thick, formed during the pit-dwelling period. In this, at a depth of 9·3 metres, a rectangular house foundation was discovered; but, apart from this, the site was marked from 9·1 to 9·3 metres by the contours of pit-dwellings. The pits are varied in shape, but the majority are round. There are cases of two pits connected by a neck. Apparently the pits were floored from time to time with a layer of clean clay, and in one case traces of reed walling or flooring were found.

In the same stratum as the pit-dwellings a tholos tomb was discovered with a dromos of unusual length approaching it. It contained nine skeletons. The tomb was roughly circular and 1·5 metres in diameter. It was probably roofed over with a wooden structure; for across the skeletons were traces of wooden beams charred or oxidised. Owing to the number of skeletons, in such a confined space, it was impossible to determine their original position or to allot the bones to individuals. One skeleton, however, it could be seen, lay on its face with the head turned on the left cheek and the left arm doubled beneath. All the heads, with two exceptions, were around the wall of the tomb, the feet to the centre. Interment was not simultaneous. The skulls, which are in a good state of preservation, differ in type, but have not yet been examined by an expert. This is not the first discovery of human remains on the site; but a skeleton, found in 1911 in a crouched position at a depth of 8·75 metres, was destroyed during the War. A number of fragments of skulls have been found at varying depths during the last three years, but they have been too small to afford any opportunity for drawing a conclusion from them.

The practice of burying the dead in the town and not in a separate graveyard can be paralleled at Sesklo (Thessaly), and in pre-Mycenæan times in the Ægean on Melos (Phylakopi). Another point in common with the Ægean is the interment of a number of persons in the same tomb.

The resemblance between the tombs of the Ægean and Vinča becomes the more striking and important in the light of a number of analogies and resemblances in other finds. This is especially marked in the plastic art. The type of head and face on the Vinča terra-cotta statuettes is the same as that of the Cycladic marble statuettes. One head shows exactly the same perforations as are found in the so-called Egyptian dolls of the XIIth Dynasty. Vases in the form of human or animal bodies, or ornamented with human representations, are numerous. A naked female figure recalls the naked goddess of Kadesh, while it is to be remembered that Egyptian girls until puberty wore a belt only. Again, the Hyde vase found last year has early analogies only in Egypt. These occur there as early as the Vth Dynasty, while in the Ægean they do not appear until the Greek Archaic period, apparently copied from Egypt. Vinča was thus in touch indirectly with Egypt, the Ægean affording the link.

A prosopomorphous lid, showing two diametrically opposed faces, points to Cyprus, double rhytons to Enkomi in Cyprus and farther afield to Assyria. Small offering tables with circular depressions, and all the more important forms of pottery, have analogies in the Ægean. They occur at Vinča from the earliest time, the pit-dwelling period. The technique of ornamentation on fragments from the black stratum, in which the finger or a special tool was used in marking a thin slip, seems to be an imitation of the barbotin technique of Knossos, *MMa* and *MMb*. If this supposition be correct, it affords valuable evidence for dating the commencement of the Vinča settlement.

These and other finds bear witness to the high civilisation of Vinča. The settlement would appear to have been due to colonists choosing this point on the Danube for the exploitation of the mineral wealth around Avala Peak. These minerals were galenite, cinnabar, and an ore which it is proposed to call avalite, a silicate of chromium which was used as a cosmetic, producing the green colour which in Egypt was obtained for the identical purpose from malachite. There is evidence to show that the cinnabar was worked at Vinča for red colouring matter, while the galenite was used instead of antimony as a cosmetic, though lead may also have been extracted from it. It is also possible that part of the silver found at Troy II and in Crete *EM* III and *MM* I may have been obtained in the country around Vinča.

Chemistry of the Vitamins.

A DISCUSSION on the chemistry of the vitamins and related substances in Section B (Chemistry) of the British Association on Sept. 25 was opened by Sir F. Gowland Hopkins, who referred to the difficulties which have attended all attempts at the isolation or determination of the constitution of the vitamins, and then discussed the general nutritional importance of the vitamins and the extremely small concentrations at which they are effective. There are marked differences in the constitution of the vitamins. All doubts as to the individuality of vitamin A and vitamin D have now disappeared, and in general, deficiency of either of these vitamins gives a totally distinct picture in the animal. The discussion of the establishment of biological standards by an international committee in London has indicated that we have now a technique capable of practical results, and the physiologist's next task is to determine the mechanism of the action of the vitamins in the human body. Success in this field will undoubtedly reveal a good deal more about the body itself.

Prof. P. Karrer, in opening the discussion on vitamin A and the carotinoids, said that two of the ten basic substances at present known to belong to the carotinoid group of yellow pigments are hydrocarbons, lycopene and carotene, having the composition $C_{40}H_{56}$. The results of oxidation experiments indicate that lycopene has an open chain with thirteen double linkings. Carotene occurs in two modifications, the α-modification being highly optically active, while the β-form is inactive. The two isomers differ in melting point and absorption spectra, and isomerism is probably due to different arrangements of the double bonds, both carotenes containing eleven double bonds and two cyclohexene rings, substituted with methyl groups in the 2 : 2 : 6-positions relative to the chain. They may possibly be derived from lycopene by ring closure. Partial hydrogenation of the carotenes yields the dihydrocarotenes. Carotene is not identical with vitamin A from cod-liver oil, although highly active preparations of vitamin A on ozonisation, like carotene, give geronic acid, and vitamin A of cod-liver oil accordingly may contain in its molecule the same pseudo ionone system as carotene and a hydroxyl group, being an oxidation product of carotene.

Biochemical experiments with carotenes and vitamin A described by Prof. H. von Euler have indicated that two forms of carotene exist in plants and a third isomeride can be regenerated from carotene triiodide. Accordingly, it is suggested that there are several fat-soluble factors of the vitamin A type, and concentrates with an extremely high biological activity giving a Carr-Price reaction more than a hundred times as strong as carotene have been prepared. Prof. R. Kuhn described the methods elaborated for the preparation of α-carotene, and the effect of carotene preparations on the growth and liver oils of rats; and Dr. T. Moore contributed a further account of experiments in which the vitamin A content of the liver oil of rats has been increased to about 100,000 B.U. for the entire liver, equivalent to a century's supply at the minimal curative dose, by feeding rats with either carotene or preformed vitamin A. The individual liver oils gave colour values as high as 600 B.U. per mgm. After saponification and removal of the crystalline matter, concentrates having values of 1200 to 2000 B.U. per mgm. were obtained, the final values being largely independent of divergent values of the samples before saponification. The results indicated that conversion of the carotene was accompanied by at least a tenfold increase in colour value. The best concentrates, however, did not appear to be more than two to three times as active as crystalline carotene.

The constitution of lycopene resembles that of squalene, and Prof. I. M. Heilbron and Dr. R. A. Morton have found that fish and mammalian liver oils and concentrates show an absorption band in the ultra-violet (maximum 328 μμ) varying in intensity over the range 1-20,000, which can be determined to within ± 5 per cent. Spectroscopic evidence shows that liver oils contain two chromogenic substances which behave as separate entities, although kinship is not excluded. The 328 μμ band and the 562-583 μμ band in the antimony trichloride colour test are valid quantitative criteria of vitamin A potency. Available evidence regarding the molecular weight of vitamin A and the percentage of inactive substances in the richest concentrates indicates a very high molecular extinction coefficient at 328 μμ, and a chromogenic value for the intensity of the blue colour with antimony trichloride many times greater than that of any known sterol or carotinoid.

The afternoon discussion was devoted to a discussion on the chemistry of vitamin B and related problems. Prof. B. C. P. Jansen opened with an account of the method by which he and Dr. Donath isolated the anti-neuritic B_1 vitamin from rice polishings. Only about 30 mgm. of pure B_1 vitamin hydrochloride were obtained from 100 kgm. after several months' work, but replacement of the phosphotungstic acid by silico-tungstic acid gave a much better yield. Dr. R. A. Peters reviewed the various methods of separating and concentrating the vitamin B complex. Vitamin B_1, like B_4 and B_5, is soluble in absolute alcohol as hydrochloride but insoluble in lipoid solvents. It is stable to acid hydrolysis, even to boiling nitric acid, and is also resistant to benzoylation, oxidation, and reduction and treatment with nitrous acid. It is inactivated by alkali, and the view that B_1 is a tertiary base is further supported by its absorption on charcoal at *p*H 9·0. Vitamin B_4, which is liable to accompany B_1, is differentiated by prior adsorption on charcoal at acid hydrogen ion concentration, and by the wide divergence in the ratio B_1/B_4 in different dilute aqueous and alcoholic hydrochloric acid extracts. It is precipitated by mercuric sulphate, and destroyed on prolonged treatment with nitric acid. Vitamin B_5 follows B_1 in phosphotungstic fractionation and is probably basic. It is more stable to alkali than B_3. Vitamin B_3 is not extracted from the wheat germ by warm dilute 97 per cent alcohol, and although resistant to heat and acid hydrolysis when combined, rapidly disappears when liberated from combination.

In a discussion on the chemistry of vitamin D and related sterols, Mr. R. B. Bourdillon and Drs. E. H. Reerink and A. van Wijk dealt with crystalline preparations of highly antirachitic substances, the latter describing the isolation of a crystalline antirachitic reaction product, m.p. 115°-117°, by irradiation of ergosterol in pure peroxide-free ether. This product is not very stable in solution *in vacuo*, and oxidises very rapidly in presence of oxygen. Its physical properties vary somewhat with the exact isolation conditions. It is possible that the three products isolated by these workers and by Prof. A. Windaus are mixtures of different proportions of two nearly isomorphic antirachitic compounds, one being fairly stable and dextrorotatory, and the other less stable and lævorotatory or slightly dextrorotatory.

Prof. I. M. Heilbron and Mr. J. C. E. Simpson described the preparation of a series of ergosteryl ethers. Ergosteryl methyl ether closely resembles ergosterol itself as regards colour reactions and absorption spectra, but does not yield an antirachitic product on irradiation, an observation which points to the necessity of the free hydroxyl group for the production of the antirachitic vitamin.

Phosphorescence of the Sea.

AN important article on the "Phosphorescence of the Sea" appears in the *Marine Observer* for November, which is published by the Marine Division of the Meteorological Office. Nothing is in reality known about this mysterious phenomenon, save that it is associated with floating animals, and possibly at times with floating plants. During the eleven years 1920–30, some 2200 observations were recorded and the localities of these are charted. The number of reports is affected by the number of observing ships and the lines of the main steamship tracks. But, even making due allowance for these and for the few routes across the Pacific, phosphorescence would seem to be more general near the sides of the oceans and of more frequent occurrence in the warm tropical seas. Thus in the Arabian Sea, which fulfils both these conditions, there are 500 records between the Red Sea and Ceylon, with a special preponderance near the ends of the line. Here monthly graphs show the largest percentage of observations in August, which is about midsummer in the water, but it is also the season of maximum forces of the currents of the East African and West Indian coasts.

The number of displays of phosphorescence in each month along a section across the North Atlantic from Newfoundland to the Bay of Biscay would also seem to fit in with the seasons when the great drift current of the Atlantic is at its strongest, namely, July to August to the east, and March to April to the west. Further support to this theory of the association of currents and phosphorescence is given by the figures shown in the counter equatorial currents, and there would seem also to be possible relationships with currents near Japan and in the Great Australian Bight.

The theory is that currents are carrying the floating animal life that produces the phosphorescence into new areas where it does not normally live, though why it should be stimulated to give its displays is unknown. It would appear that most of the animals in these currents are being carried to destruction, but the presence of differentiated phosphorescent organs in most forms is not consistent with its display being a morbid factor. Phosphorescence varies from sparks of light to a milkiness which may make every part of the deck visible and often fades to a multitude of globes beneath the surface of the sea. All variants of display may be found even in the same region, but we are not yet able precisely to associate the nature of the light with the phosphorescent animals. Why in one condition of the sea no phosphorescence is seen while in another it is brilliant—collections of the surface fauna showing precisely the same organisms—is quite unknown.

Acoustical Problems of Broadcasting Studios.

THE world-wide interest in broadcasting has, during the last seven years, stimulated research on architectural acoustics. An excellent survey of the result was given by N. Ashbridge in a paper on the "Acoustical Problems of Broadcasting Studios", read before Section G of the British Association in London on Sept. 25, and printed in full in *Engineering* for Oct. 16 and 23.

Although economic and practical considerations frequently prevent the adoption of an ideal specification, particularly when a studio has to be made in a building not designed for the purpose, in a new building, such as the Broadcasting House of the B.B.C. in Langham Place, London, almost ideal surroundings are provided for many of the studios. Continuous steel-frame construction is avoided, so as to prevent transmission to the studio of noises from other studios or from machinery. Traffic noises are excluded by the absence of direct openings to the street, fresh air being provided by a quiet ventilating plant serving one studio only, to prevent sound travelling along air-ducts from one studio to another. Walls, floor, and ceiling of a studio are made sufficiently rigid to avoid their tendency of acting as flexible diaphragms. Empirical rules have been found governing the shapes and sizes of studios and their reverberation periods.

It has been found that the physical property that determines almost entirely the value of the reproduction is the reverberation period, which should always be the same for a given size of hall. Although a small studio can readily be built to have plenty of room for an orchestra and a reverberation period of the same value as a concert hall, the intensity of sound in such conditions is often sufficient to be unpleasant for the performers and to overload the microphone. In a good studio the reverberation period is constant to within 20 per cent for all frequencies between about 40 and 10,000 cycles, although practical measurements usually cover only the range from 100 to 6000 cycles per second.

Many Continental studios have walls fitted with shutters having different surface treatment on each side, so that the reverberation period of each studio is variable. In Hamburg the volume of the studio can also be changed by moving the position of one end wall. The range of intensity of sound that can be tolerated by transmitter or receiver is less than half that produced by an orchestra. The position of the microphone in relation to the instruments of an orchestra involves complex factors.

University and Educational Intelligence.

CAMBRIDGE.—The following appointments have been made: A. E. Watkins, St. John's College, University lecturer in cytology; Dr. E. J. Maskell, Emmanuel College, University lecturer in plant physiology; W. J. Dowson, Christ's College, University lecturer in mycology; G. C. Grindley, University demonstrator in experimental psychology, and E. H. B. Boulton, St. Catharine's College, University lecturer in forestry (re-appointment).

H. R. Barnell, Downing College, has been appointed to the Frank Smart University Studentship in Botany.

The governing body of Emmanuel College invites applications for a research studentship which will be awarded in July 1932. Applications must be sent to the Master, Emmanuel College, Cambridge, in time to reach him not later than June 30, 1932. Preference will be given to candidates who have already completed one but not more than two years of research. The studentship, which must be held at Emmanuel College, and has a maximum annual value of £150, is awarded and normally held for two years. The successful applicant must be admitted by the University of Cambridge as a Research Student and begin residence in October 1932.

NOTICE is given by the Institution of Chemical Engineers that application forms for the 1932 examination for the associate-membership of the institution must be returned to the Hon. Registrar, Abbey House, Westminster, S.W.1, by Dec. 21. Copies of the application form and a memorandum on "The Training of a Chemical Engineer" are obtainable from the Hon. Registrar.

THE Chemical Society announces that applications for grants from its Research Fund must be made on forms obtainable from the Assistant Secretary, Burlington House, W.1, by, at latest, Dec. 1. It gives the reminder that the income arising from the donation of the Goldsmiths' Company is to be more or less especially devoted to the encouragement of research in inorganic and metallurgical chemistry, and that the income from the Perkin Memorial Fund is to be applied to investigations relating to problems connected with the coal tar and allied industries.

APPLICATIONS for the following research fellowships for women are invited by the British Federation of University Women, Crosby Hall, Cheyne Walk, S.W.3:

a Senior International Fellowship in mathematics, physics, chemistry, geology, and biological sciences (including physiology and pathology), value £250 (offered by the International Federation of University Women); an American International Fellowship, value 1500 dollars (offered by the American Association of University Women); an International Residential Scholarship at Crosby Hall, value £100 (offered by the British Federation of University Women); a Swiss Research Fellowship in arts (including theology and jurisprudence), value 4000 Swiss francs (offered by the Swiss Association of University Women); a Rose Sidgwick Memorial Fellowship, value 2000 dollars; and an Ellen Richards Research Prize, value 2000 dollars.

THE German university system is discussed in a report, published in the October number of the *Universities Review*, of a commission of investigation appointed by the Association of University Teachers. The materials for the report were gathered by a party of university teachers from Aberystwyth, Birmingham, Cardiff, Cork, Exeter, Liverpool, London, Manchester, Nottingham, and Oxford in the course of a tour in Germany during the Easter vacation, the universities visited being Berlin, Göttingen, and Hamburg. Among present-day tendencies noticed in the report is the increasing emphasis on 'bread-and-butter' studies at the expense of the traditional function of the university as a training ground in philosophic method. This is attributed to the revolution and the consequent freer entrance to and overcrowding of the universities, and the growth of unemployment. The large post-War increase in the numbers of students is also responsible for fostering the growth of an examination system somewhat similar to that of Great Britain, and for restricting individual contact between teachers and taught. Interest in physical training has developed notably since the abolition of compulsory military service, and some universities require all students to attend, unless medically exempted, during two semesters at the highly organised physical training courses provided. The complete absence of tutors and similar advisers is referred to as a disadvantage, only partially overcome by the issue of booklets containing advice to students, and by *Fachgemeinschaften* societies for establishing closer academic contacts between staffs and students working for the same examinations, and providing opportunities for joint discussions. The report is a sequel to a similar report prepared last year on the French university system.

THE Bradford Education Committee has published a *Journal of Research* of the Bradford Technical College (vol. 1, 1930, pp. xii + 295). "I am anxious", says the chairman of the Technical Education Sub-Committee in the foreword, "that the volume of research in the College shall increase. I hope that the bi-annual publication of this journal will be possible"—hopes in which everyone interested in the importance of strengthening the link between technical education and industry will join. Far too little is known of the research work which proceeds steadily in technical institutions. Nor has the full capacity for research of which they are capable been yet realised by the institutions themselves. This volume will, we hope, range industrialists still further on the side of those who would break down the barriers which tend to prevent research development in technical institutions —regulations governing the superannuation of teachers form one of them. The majority of the papers now drawn together have previously appeared in various scientific publications. Well printed and clearly illustrated, they show powerfully the wide scope of the work carried out in one of our large technical institutions; they include descriptions of research carried out in practically all departments—textiles, chemistry, physics, mathematics, mechanical and electrical engineering. Invidious as it may be to name any of the papers which make up the volume, nevertheless its scope can better be seen if we indicate: "Bradford and Continental Systems of Yarn Manufacture", "Decomposition of Substituted Carbamyl Chlorides by Hydroxy-Compounds", "A Graphical Analysis of Stress", "The Measurement of the Voltage Amplification Factor of Tetrodes", "Refraction and Dispersion of Gaseous Carbon Disulphide", "Note on Green's Lemma and Stokes's Theorem".

Societies and Academies.

LONDON.

Society of Public Analysts, Nov. 4.—**W. R. Schoeller** and **C. Jahn**: A reliable method for the quantitative separation of titanium from tantalum and niobium. The oxalate salicylate method for the separation of titania from the earth acids has now been perfected, with the result that an almost quantitative recovery of the earth acids is achieved, and that less than 1 mgm. of titania remains in the final pentoxides. The process is claimed to be accurate within 0·5 per cent.—**E. F. Waterhouse** and **W. R. Schoeller**: The separation of the earth acids from metals of the hydrogen sulphide group. The separation of tantalum and niobium from antimony, bismuth, and copper was studied. When the mixed oxides were fused with bisulphate, the mass dissolved in tartaric acid, and the clear solution treated with hydrogen sulphide, the sulphide precipitate was always found to be contaminated with earth acid. The co-precipitation is ascribed to hydrolytic decomposition of the tartaric earth-acid complexes. The separation is completed by further treatment of the sulphide precipitate.—**J. Reilly**, **N. Noonan**, and **P. J. Drumm**: The evaluation of the menthone content of peppermint oil. A method of determining menthone as its semicarbazone is described. In test experiments with pure menthone the results were approximately ninety-five per cent of the theoretical amount.—**D. M. Freeland**: The determination of vanillin in chocolate and cocoa butter. A 2 per cent solution of ammonia in 95 per cent alcohol is used to extract vanillin from cocoa butter, the extracts are evaporated at 70° C. to remove alcohol, the aqueous solution is extracted with ether, the ethereal extracts purified and evaporated at a low temperature, and the residue of crude vanillin dried and weighed. A volumetric method of determination is also described. For chocolate, the fat is first extracted with petroleum spirit.—**H. R. Ambler**: The direct determination of nitrogen in gases. All gases other than nitrogen are removed with only one manipulation of the sample, by (1) burning the combustible constituents in a regulated stream of electrolytic oxygen, and (2) absorbing the excess of oxygen by introducing pyrogallol into the same vessel in the presence of the gas. The residual gas, consisting of nitrogen, is then directly measured. A special combustion vessel is used.

PARIS.

Academy of Sciences, Oct. 5.—**Emile Picard**: The fifth general meeting of the International Research Council.—**L. Massoutié**: Fermat's last theorem.—**Jacques Herbrand**: The theory of bodies of numbers of infinite degree.—**F. Leja**: A property of series of polynomials.—**Bertrand Gambier**: The simultaneous integration of two differential equations of the first order.—**W. Fédoroff**: A characteristic property of monogene functions.—**Kiveliovitch**: Shocks in the problem of a body attracted by two fixed centres.—**Lucien Féraud**: Properties resulting from the arithmetical nature of characteristic exponents.—**Jean Louis Destouches**: An equation of quantum mechanics.—**A. Grebel**: Automatic self-tightening bolts. A general discussion of the subject showing that the faults of existing devices are in part due to failure to grasp the problem as a whole.—**R. de Mallemann**: The molecular theory of electro-optical phenomena.—**A. Piccard, E. Stahel, and F. Dony**: The absorption of the penetrating gamma rays by lead screens 12-30 cm. thick. In the case of the thickest screen, allowing the passage of less than one millionth of the original gamma rays, a preparation of 6 grams of elementary radium was employed. There was no evidence of an ultra-penetrating component. This result, combined with the fact that at an altitude of 16,000 metres gamma rays are found, is contrary to the hypothesis according to which the cosmic rays would be the penetrating part of an ordinary radioactive effect.—**Ch. Bedel**: The electromotive forces developed between silicon and some substances in solution in hydrofluoric acid, sulphuric acid, and soda.—**Charles Dufraisse and Marius Badoche**: Researches on the coloured hydrocarbons: a violet hydrocarbon $C_{36}H_{22}$. This hydrocarbon is obtained by removing two atoms of hydrogen from dephenylorubrene.—**André Meyer and Robert Vittenet**: The azomethines of homophthalimide and its *N*-aryl derivatives.—**S. Goldsztaub**: The dehydration of the natural ferric hydrates.—**Jacques Bourcart**: Some new data on the problem of the limit between the Moroccan Haut-Atlas and Moyen-Atlas.—**Henry Hubert**: Researches on the climatology of French West Africa.—**L. Grigorakis**: The morphology and cytology of the Actinomyces.—**R. Argaud**: Veins with ribbed wall.—**Ouang Te Yio**: The physiological nature of the diastase secreted by the eclosion gland in the Plagiostomes (*Scylliorhinus canicula*). This diastase resembles trypsin, and acts in neutral or faintly alkaline medium. It acts at a much lower temperature than trypsin.—**A. Perrier**: Researches on the rôle of pectinase in the fermentation of coffee.—**A. Blanchetière**: The action of trypsin on solutions of monoamino acids, isolated or mixed.—**G. Dinulescu**: A larva of the gad-fly producing tumours in the duodenum of horses in Spain.

BRUSSELS.

Royal Academy of Belgium, April 11.—**Paul Stroobant**: The rotation of the galaxy and the solar apex shown by the radial velocities of the helium stars. A study in 1926 of the distribution of the radial velocities of the helium stars has led to the indication of a movement of translation of the whole of these stars.—**E. De Wildeman**: Concerning the northern limit of the tropical forest in the Mele region (Belgian Congo). Study of the causes of the contraction of the virgin forests in this region.—**M. Dehalu**: The observation of the total eclipse of the moon on April 2, 1931, at Cointe. The end of the totality was found to be $8^h\ 54^m\ 2^s$ by direct observations: from photographs the values $8^h\ 54^m\ 45^s$ and $8^h\ 54^m\ 41^s$ were obtained by two different methods of measurement.—**Th. De Donder**: Affinity (2). Fourth communication.—**Lucien Godeaux**: (1) Involutions of the second order of space. (2) The canonical pencil of a surface.—**A. C. Seward**: Some late Palæozoic plants from the Belgian Congo.—**Constant Lurquin**: The extension of the Bernoulli-Poisson law.—**Ray, M. Bouillenne and P. Prévot**: A plant association with *Empetrum* in the Fagnes de Clefay.—**Mlle. M. Charpentier**: The extension of Baire's problem to certain dependences considered in the theory of differential equations.—**J. Genard**: The scheme of levels of the diatomic vapour of sulphur.—**P. Gilard**: The ultra-violet transmission of glasses. A systematic study of glasses in which the proportion of one ingredient was varied. The influence of the addition of rare earths (cerium, didymium, neodymium, lanthanum) was also examined: these were not found to be specially favourable to the transmission of ultra-violet rays. The presence of the oxides of iron and manganese was found to be definitely unfavourable to the passage of the ultra-violet.—**R. H. J. Germay**: The calculation of the elliptical elements in the determination of the orbit of a planet from three observations.—**R. Deaux**: Conical helices.—**Mlle. G. Schouls**: The study of dynamic azeotropism.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, Vol. 17, No. 7, July 15).—**Wilder D. Bancroft, J. W. Ackerman, and Catharine Gallagher**: Optical sensitisation. Grotthuss (1818) showed that an alcoholic solution of ferric chloride is reduced by sunlight; the alcohol reacts with the chloride preventing the reverse action. Similarly, solutions of ferric chloride and silver nitrate free from organic matter are reduced by light when light-sensitive dyes are added. Optical dyes in photography are light-sensitive and adsorbed by silver bromide, and they are, or become, reducing agents capable of reducing the bromide.—**Wilder D. Bancroft and G. H. Richter**: Reversible coagulation in living tissue (4). The chronaxie of the nerve portion of a frog muscle-nerve preparation—that is, duration of stimulus required to produce an effect where the voltage is twice the minimum effective voltage (Lapicque)—first decreases and then increases with addition of a coagulating solution. Chronaxie of both nerve and muscle passes through a maximum with varying hydrogen ion concentration at about the isoelectric point for many proteins. These results support Claude Bernard's view that anæsthesia is due to reversible coagulation of nerve protein.—**R. E. Bowen**: The cupula of the ear. A mucilaginous substance coagulates on the crista under the action of fixing agents to form the so-called cupula. The cupula does not exist as a definitely formed structure in the living ampulla. The tectorial membrane may similarly be a coagulation product.—**B. R. Coonfield**: The cilia of *Naphthys bucera*.—**F. D. Murnaghan and A. Wintner**: A canonical form for real matrices under orthogonal transformations.—**R. B. Lindsay**: Wave motion and the equation of continuity.—**Edwin H. Hall**: Electric conductivity and optical absorption in metals (supplementary).—**Benedict Cassen**: Electromagnetic fields derived from non-commutating potentials.—**Howard B. Frost**: Uncomplicated trisomic inheritance of purple verus red in *Matthiola incana*.—**Ralph E. Cleland**: The probable origin of *Œnothera rubricalyx* " Afterglow " on the basis of the segmental interchange theory.—**Nelson F. Waters**: Inheritance of body weight in domestic fowl. The Light Brahma breed is about twice the weight of the Single Comb White Leghorn, and breeding tests with these races suggest that the difference in weight between the breeds depends primarily on two pairs of factors, each of which affects the weight of the individual equally, and which together have cumulative effects. A genetically big bird grows more rapidly and more persistently than a genetically small bird, and hybrids are intermediate except in so far as they are affected by hybrid vigour. Maximum hybrid vigour seems to go with the completely heterozygous condition of all its allelomorphic pairs of genes and vice versa.

Diary of Societies.

FRIDAY, November 13.

Biochemical Society (at Imperial College of Science and Technology), at 3.—T. Moore: High Potency Vitamin A Concentrates.—S H. Piper: X-Ray Analysis of Certain Long Chain Paraffins, Ketones, and Alcohols.—A. C. Chibnall: The Metabolism of Plant Waxes.—G. H. Bell and A. R. Craig Paterson: A Chart for *p*H Calculations.—J. A. B. Smith: The Glyceride Fatty Acids of Certain Forage Grasses.—C. R. Harington and S. S. Randall: Synthesis and Properties of *l*-β-Hydroxyglutamic Acid.—W. L. Davies: The Inactivation of Lipase in Dairy Products by Traces of Heavy Metal Salts.—J. Pryde and R. T. Williams: The Structure of Borneol Glucuronic Acid Synthesised *in vivo*.—T. S. G. Jones and E. T. Waters: A Note on the Sugar of the Nucleic Acid of *Bacillus Tuberculosis*.—H. J. Phelps: The Influence of Hydrogen-ion Concentration on the Response of Tissues to Histamine.—P V. McKie: The Nitrogen Metabolism of the Lupin Seedling —A. C. Chibnall and R. G. Westall: The Estimation of Glutamine in the Presence of Asparagine —J. M. Gulland and W. H. Newton: Observations on the Purification of the Oxytocic Principle of the Posterior Lobe of the Pituitary Gland.—*Demonstrations*:—S. H. Piper and A. C Chibnall: Apparatus for Distillation in High Vacuo of Substances with a High Melting Point.—G. H. Bell and A. R. Craig Paterson: A Chart for *p*H Calculations.

Royal Society of Arts (Indian Meeting), at 4.30.—Lt.-Col. M. L. Ferrar: The New Penal System in the Andamans.

Royal Society of Medicine (Clinical Section), at 5.30.

Malacological Society of London (at Linnean Society), at 6.—Prof. A. E. Boycott, C. Oldham, and A. R. Waterston: A Trip to Kerry.—N. H. Odhner: New and Little Known African Land Shells.—Prof. S. Hirase: The Adaptive Modifications of *Stilifer celebensis* Kuk.—F. F. Laidlaw: Notes on Zonitidæ from the Malay Peninsula with Descriptions of New Genera.—A. E. Ellis: The Habitats of Hydrobiidæ in the Adur Estuary.

North-East Coast Institution of Engineers and Shipbuilders (at Mining Institute, Newcastle-upon-Tyne), at 6.—J. W. Hobson: The Care and Maintenance of the Industrial Steam Locomotive.

Institution of Electrical Engineers (London Students' Section), at 6.15.—W. A. Bishop · Short Wave Transmission.

Institution of Welding Engineers (at Chamber of Commerce, Birmingham), at 7.—E. W. Thompson and A. Jeavons: Some Details of the Progress reached in Forge and other Welding in Boiler Works Practice.

Manchester Association of Engineers (at Engineers' Club, Manchester), at 7.15 —J. E. Hurst: A Comparative Study of the Properties of British Pig Irons.

Junior Institution of Engineers, at 7.30.—Annual General Meeting.

Keighley Association of Engineers (at Queen's Hotel, Keighley), at 7.30.—E. Clegg: The Industrial Smoke and Grit Problem.

Institute of Metals (Sheffield Local Section) (at University, Sheffield), at 7.30.—E A. Smith: Engineering Silver Solders.

Society of Chemical Industry (Chemical Engineering Group) (at Chemical Society), at 8.—D. McDonald: Platinum.

Royal Society of Medicine (Ophthalmology Section), at 8.30.—R. Gunn: Some Points in the Fitting of Contact Glasses.—F. Ridley: The Use of Antiseptics.

SATURDAY, November 14

British Mycological Society (in Botanical Department, University College), at 11 a.m.—Dr. B Barnes: Some Aquatic Fungi new to Britain.—T. H. Harrison: A Species of *Lambertella* Parasitic on Apple. —Prof. N. J. G. Smith: Some of the More Curious South African Fungi.—Dr. R. G. Tomkins: Measuring Germination.

Royal Institution of Great Britain, at 3.—F. E. Yerbury: Present-Day Architecture on the Continent; Modern Buildings in Scandinavia.

MONDAY, November 16.

Institution of Electrical Engineers (Mersey and North Wales (Liverpool) Centre) (at University, Liverpool), at 7.—Prof. E. W. Marchant: Oscillographs.

Royal Institute of British Architects, at 8.—H. S. Goodhart-Rendel: Modern European Architecture.

Royal Geographical Society, at 8.30.—W. S. Barclay: The Basin of the Parana.

TUESDAY, November 17.

Royal Institution of Great Britain, at 5.15.—Prof. J. B. S. Haldane: New Light on the Origin of Species (1).

Royal Statistical Society (at Royal Society of Arts), at 5 15.—R. G. Glenday: Business Forecasting: A Quantitative Investigation of the Influence of Money on Trade Development.

Royal Society of Medicine, at 5.30.—General Meeting.

Zoological Society of London, at 5.30.—Secretary: Report on the Additions to the Society's Menagerie during the month of October

1931.—H. R. Hewer: Studies in *Zygæna* (Lepidoptera): (*a*) The Female Genitalia; (*b*) The Male Genitalia.—Dr. F. Gwendolen Rees: An Investigation into the Occurrence, Structure, and Life-Histories of the Trematode Parasites of Four Species of *Lymnæa* and of *Hydrŏbia jenkinsi* (Mollusca) in Glamorgan and Monmouth.—Dr. Awadh Behari Misra: On the Internal Anatomy of the Male Lac Insect, *Laccifer lacca* Kerr.—W. S. Bristowe: (*a*) A Preliminary Note on the Spiders of Krakatau; (*b*) The Mating Habits of Spiders, and a Description of a New Thomisid Spider from Krakatau; (*c*) Spiders of the Farne Islands.—Dr. G. S. Sansom: Notes on Some Early Blastocysts of the South American Bat *Molossus*.

Institution of Civil Engineers, at 6.—H. C. Whitehead and F. R. O'Shaughnessy: The Treatment of Sewage Sludge by Bacterial Digestion.

Royal Aeronautical Society (Students' Section) (at 7 Albemarle Street), at 6.30.—Prof. L. Bairstow: Applications of Aeronautical Research.

London Natural History Society (Botany Section) (at London School of Hygiene and Tropical Medicine), at 6.30.—J. Ross: Common Wall Mosses.

Institution of Electrical Engineers (East Midland Sub-Centre) (at College, Loughborough), at 6.45.—N. B. Rosher: Address.

Institution of Automobile Engineers (Wolverhampton Centre) (at Seagrave Club, Wolverhampton), at 7.30.—B. G. Robbins: The Training of Young Automobile Engineers.

Royal Society of Arts, at 8.—M. Hochstadter, W. Vogel, and E. Bowden: The Pressure Cable: An Advance in the Construction of High Voltage Cable Installations.

Royal Aeronautical Society (Bristol Branch).—Major J. S. Buchanan: High Speed Aircraft.

Royal Photographic Society.—J. Reid Moir: Ancient Men in East Anglia.

WEDNESDAY, November 18.

Society of Glass Technology (at University, Sheffield), at 2.

Royal Meteorological Society, at 5.—J. E. Clark, I. D. Margary, R. Marshall, C. J. P. Cave, and L. C. W. Bonacina: Report on the Phenological Observations in the British Isles, from December 1929 to November 1930.—Sir G. T. Walker and A. C. Phillips: The Forms of Stratified Clouds: Part 1, Experimental; Part 2, Discussion.—W. Dunbar: Eighty Years Rainfall at North Craig Reservoir, Kilmarnock.

Royal Microscopical Society (at B.M.A. House, Tavistock Square), at 5.30.—Conrad Beck: The Substage Diaphragm and its Functions.—Dr. A. A. Tarkhan: The Effects of Fixatives and other Reagents on Cell-size and Tissue-bulk.

Geological Society, at 5.30.—Prof. A. C. Seward: (*a*) Fossil Plants from the Bokkeveld and Witteberg Beds of South Africa; (*b*) Carboniferous Plants from Sinai.—Dr. T. N. George: The British Carboniferous Reticulate Spiriferidæ.

Illuminating Engineering Society (at 4 Dowgate Hill, E.C.4) at 7.—R. H. Monier-Williams: The Tallow Chandlers' Company and their Craft.—W. J. A. Butterfield: The Historical Development of Gas Lighting.—J. Swinburne: The Early Days of Electric Lighting.

Institution of Automobile Engineers (Leeds Centre) (at Hotel Metropole, Leeds), at 7.15.—B. G. Robbins: The Training of Young Automobile Engineers.

North-East Coast Institution of Engineers and Shipbuilders (Graduate Section) (at Bolbec Hall, Newcastle-upon-Tyne), at 7.15.—W. Pratt: Turbine Gearing.

Linstead: Investigations of the Olefinic Acids. Part VI. Lactonisation and Allied Additive Reactions. Part I. The System, αβ-acid-βγ-acid-γ-lactone.

Royal Society of Tropical Medicine and Hygiene (at Hospital for Tropical Diseases), at 8.15.—Clinical and Laboratory Meeting.

British Institute of Radiology, at 8.30.—Dr. F. Roberts: Some Criticisms of the International Protection Recommendations.—G. E. Vilvandre: The Radiology of Gall-stones and the Gall-bladder.

Institution of Mechanical Engineers (Manchester Centre) (at Manchester).—Ll. B. Atkinson: The Mechanical Aspects of Electricity (Thomas Hawksley Lecture).

FRIDAY, November 20.

Royal Society of Medicine (Physical Medicine Section) (at British Red Cross Clinic, Peto Place, N.W.1), at 5.

Physical Society (at Imperial College of Science), at 5.—Miss F. Lowater: The Band Spectrum of Zirconium Oxide.—W. A. Wood: Lattice-distortion of Cold-drawn Constantan Wire.—Dr. F. Aughtie: (*a*) A Remote Electrically Recording Accelerometer with Particular Reference to Wheel-impact Measurements; (*b*) A Remote Electrically Recording Load-gauge for Wheel-impact Measurements.—Prof. E. V. Appleton and G. Builder: Wireless Echoes of Short Delay.—Kerr Grant: *Demonstrations*:—A Contrivance for Demonstrating the Law of Errors; a New Type of Surface-tension Meter; and a New Type of Static Electrometer.

Society of Chemical Industry (Liverpool Section) (at University, Liverpool), at 6.—Prof. I. M. Heilbron: Nature's Variations on the Isoprene Theme.

Institution of Mechanical Engineers, at 6.—Presentation of Sixth Report of the Marine Oil Engine Trials Committee.

Society of Dyers and Colourists (at 36 George Street, Manchester), at 7.—C. M. Whittaker: Random Leaves from a Viscose Yarn Dyer's Notebook.

Society of Chemical Industry (South Wales Section) (jointly with Institute of Chemistry—South Wales Section) (at Technical College, Cardiff), at 7.30.—Dr. J. H. Quastel: Dyestuffs and Biological Activity.

Society of Chemical Industry (Glasgow Section) (at St. Enoch Hotel, Glasgow), at 7.30.—Prof. J. C. Philip: The Abstracting of Chemical Literature.

Junior Institution of Engineers, at 7.30.—H. G. Brown: Modern Pressed Brick Manufacture.

South London Botanical Institute (323 Norwood Road), at 8.—J. E. Lousley: Plant Parasites (Lecture).

Royal Society of Medicine (Radiology Section), at 8.30.—Discussion on X-ray Diagnosis of Diseases of the Chest.

Royal Institution of Great Britain, at 9.—Prof. C. H. Lander: Oil and Petrol from Coal.

Royal Aeronautical Society (Hull and Leeds Branch).—Lt.-Col. W. L. Marsh: Speed in Aviation and what it means.

SATURDAY, November 21.

Royal Institution of Great Britain, at 3.—W. Perrett: The Music of Ancient Greece (1): The Enharmonic Genus.

British Psychological Society (at King's College), at 3.—Rev. H. L. Philp: Frustration of Will Acts.—M. F. Lowe: Blood Distribution during Mental Activity.—*Demonstrations*:—A. G. Caws: Perception of Tachistoscopically Exposed Symbols.—R. Westgate: Effect of Affective Stimuli on Muscular Work.

PUBLIC LECTURES.

FRIDAY, November 13.

King's College, London, at 5.30.—J. Benda: L'exploitation de la Science par la Littérature au 19e Siècle.

Bedson Club (at Armstrong College, Newcastle-upon-Tyne), at 6.30.—Prof. J. Read: Some Researches on Essential Oils.

Chadwick Trust Lecture (at Gateshead Town Hall), at 7.30.—Sir Robert Philip. The Outlook on Tuberculosis—Then and Now.

SATURDAY, November 14.

Horniman Museum (Forest Hill), at 3.30.—M. A. Phillips: Nature at Home.

MONDAY, November 16.

University, Leeds, at 5.15.—Prof. J. B. S. Haldane: Evolution in the Light of Genetics.

Royal Anthropological Institute (at University College), at 5.30.—J. V. S. Wilkinson: Historians and Painters of the Mughal Court.

University College, at 5.30.—Prof. B. Ohlin: Some Remedies for Unemployment (Newmarch Lectures in Statistics) (1) (Succeeding Lectures on Nov. 17, 18, 19, and 20.)

Royal School of Mines, at 8.—Dr. C. J. Smithells: Metallurgy in the Electrical Industry (Armourers' and Brasiers' Company Lectures). (Succeeding Lectures on Nov. 23 and 30.)

TUESDAY, November 17.

University College, at 3.—Dr. W. Stephenson. Clinical Mental Tests.

Gresham College, at 6.—A. R. Hinks: Unanswered Questions in Astronomy. (Succeeding Lectures on Nov. 13, 19, and 20.)

Institute of Industrial Administration (at Institute of Hygiene, 28 Portland Place, W.1), at 6.30.—J. Fearn: Industrial Russia.

WEDNESDAY, November 18.

Royal Institute of Public Health, at 4.—Dr. P. Chalmers Watson: The Food of the Citizen

London School of Economics, at 6.—Dr. L. J. Comrie: Modern Babbage Machines.

Museum and Art Gallery, Belfast, at 8.—Dr. A. Mahr: Megaliths in Prehistoric Europe, with Special Reference to Irish Evidence.

THURSDAY, November 19.

Science Museum (South Kensington) (in connexion with Exhibition of Modern Glasses), at 4.45.—A. L. Marden: The Electrical Incandescent Lamp.

FRIDAY, November 20.

University College, Dundee, Scientific Society (at Dundee), at 4.30.—Prof. J. Read: An Organic Chemist looks at Australia

Institute of Chemistry, at 8.—Dr. J. V. Eyre: Recent Advances in the Fermentation Industries (Streatfeild Memorial Lecture)

SATURDAY, November 21.

Horniman Museum (Forest Hill), at 3.30.—H. St. George Gray: The Romans in the South of England.

SATURDAY, NOVEMBER 21, 1931.

Zoological Survey of India.

THE Government of India, like many other governments of the world, is at present passing through a financial crisis, and in order to balance its budget finds it necessary to effect heavy retrenchments in expenditure. Proposals for retrenchment have been submitted to Government by certain committees appointed for the purpose, composed of members of the Indian Legislative Assembly; the proposals which affect the Zoological Survey of India are contained in the Report (Interim) of the General Purposes Sub-Committee of the Retrenchment Advisory Committee (Part I.), recently published, and Sir C. V. Raman has considered these proposals in a pamphlet which he has issued entitled "The Zoological Survey of India—Memorandum on the Proposals for Retrenchment".

The Zoological Survey, instituted in 1916, inherited, as the Sub-Committee observes, the duties of the zoological and anthropological section of the Indian Museum; it acts as a guardian of the zoological collection of the Indian Empire and obtains and utilises information about the systematic and geographical zoology of India. The budget of the Survey for the present financial year is Rs. 2,30,000 (about £17,250); that proposed for next year is Rs. 60,000, about a quarter (26 per cent) of its present amount. One of the eight officers at present on the cadre of the Survey has been newly appointed for fisheries work in the Andamans; it is proposed by the Sub-Committee that this work should go on, at a cost of not more than Rs. 12,000 (about £900). The figures adopted by Sir C. V. Raman are exclusive of this allocation for fisheries; as he puts it, an annual budget of Rs. 2,18,000 is being cut down to Rs. 48,000 (£3600, or 22 per cent of this year's amount); as a matter of fact, the zoological work which is the primary reason for the existence of the Survey is in worse case than is implied by even this, since the anthropological section of the Survey, as well as the fisheries, is also to be continued and financed out of the reduced budget.

"We feel", says the Sub-Committee, "that the essential duties can still be carried on with the budget proposed by us provided that all unnecessary items of expenditure are deleted." *Prima facie* it is unlikely that "the essential duties" of any department can be carried on on a quarter (or, taking Sir C. V. Raman's interpretation, a little more than one-fifth) of its actual present-day cost; and in particular that the zoological and anthropological needs of an area the size of western Europe, with a fauna and a human population far richer and more diversified than those of Europe, can be cared for on an expenditure of £3600 per annum. Leaving entirely aside the wider duties of the Survey, mere maintenance charges—the upkeep of the collections of the Museum, the display of specimens in the galleries, the pay of clerks and attendants, the maintenance of the library (probably by far the best zoological library in the whole of Asia), including the purchase of books and periodicals as well as their care—these indispensable charges swallow up a sum which will permit the payment of the salary of only a single officer, who would be entirely occupied with the administration of the Museum; while the valuable series of the *Memoirs* and *Records of the Indian Museum* must, of course, cease immediately.

There are at present seven officers (exclusive of the one recently appointed for fishery work) on the Survey; in 1906 there were four officers in the zoological section of the Indian Museum; the number had risen from one in 1875; if the Sub-Committee's retrenchment proposals are adopted, the officers of the Survey must be disbanded, the research work of the Survey must come to an end, and the hands of the clock will be put back to a period fifty years ago.

The Sub-Committee, it is fair to say, probably does not intend this; it states that "Zoological Survey work is not normally of a systematic nature, and the work of the Universities could and should be of the nature which must overlap the activities of a Government zoological department. Further, zoological survey cannot be said to have economic value." There seems to be some misunderstanding here, or rather several misunderstandings. Zoological survey work is in the first place and above all 'systematic' (in the zoological sense), and 'systematic' zoology is not the division that either is or usually can be taken up in universities. As Sir Venkata shows convincingly, the work in universities is and must be mainly morphological; facilities for 'systematic' work—large named collections for comparison, and especially a complete and up-to-date library—do not exist at the universities, and can only be had at the Survey headquarters at Calcutta; and the teachers of zoology have neither the leisure nor, it may be added, in most cases the training, for undertaking the work of the Survey in addition to their own duties. "The functions of a State Museum of Zoology, namely, the care and preservation of the national collections, the proper arrangement of zoological exhibits in the public galleries with a view to educate the public, and research in systematic zoology, cannot be relegated to a University without seriously affecting the usefulness and efficiency of both the University and the State Museum." It may perhaps be added that even if these functions could be so relegated, they would presumably have to be paid for; and the Government of India would be paying for amateur work done by servants of other institutions what it now pays to its own experts. Further, all but one (Calcutta) of the Indian universities which grant degrees in zoology are at a distance of hundreds of miles—a number at more than a thousand—from the Museum and Survey headquarters.

Regarding the alleged economic worthlessness of zoological survey work, Sir Venkata quotes the words of the late Dr. Annandale, the first Director of the Survey: ". . . Our primary function can hardly be to conduct either morphological or economic research. These are subjects rather for the colleges of India on the one hand and for the technical departments on the other. Our investigations must be those of pioneers preparing the road along which morphologists, biologists, economic entomologists, students of fisheries, and others may travel in the future. . . . We are convinced that it is impossible to build a solid structure of practical results except on a sound basis of pure science." For readers of NATURE this point need not be laboured. The first requisite for zoological work is to know what one is dealing with; before extended zoological work of any kind is so much as possible we must know what our animals are, we must get them described, named, and classified; neither economic nor any other branch of zoology is possible otherwise; in Sir Venkata's words, "Systematic Zoology is, therefore, the bed-rock on which all zoological research, economic or otherwise, stands". Yet according to the Sub-Committee "zoological survey work cannot be said to have economic value"!

Sir C. V. Raman considers that the Sub-Committee's proposals, if carried out, mean not only the end of the Survey, but also the end of the Museum. "Anyone who has knowledge of the organisation of the Museums of even some of the smaller countries in Europe will at once realise that the proposals leave no alternative but that of breaking up and distributing the collections to those institutions that can afford the expert staff to look after them." The collections are worth crores, and while the museums of Europe and America would be only too glad to acquire them, the universities of India can neither afford them nor spare the staff and money to look after them; there is no public or private institution in India which can house even a small portion of the collections. The question of disposal, however, simplifies itself, since, under the provision of the Museum Act, the zoological and anthropological collections, except those purchased by the Government after the Zoological Survey was instituted, are the property of the Asiatic Society of Bengal, administered by the Trustees of the Indian Museum. If the Government of India terminates the trust, the collections must be handed over to the Asiatic Society or its assignees. As the Society found it necessary in 1875 to transfer all its collections to the Museum, it certainly cannot accommodate them now, after they have grown steadily for more than half a century, and they would necessarily have to be disposed of abroad.

Retrenchment on a reasonable scale, on a scale such as is contemplated for salaries, or for most of the other departments, the Survey can accept. The Department which is considered by the Sub-Committee immediately after the zoological is the archæological; a budget of 16 lakhs is here cut down to 10½—a reduction of one-third (still, however, leaving the allocation seventeen and a half times that for zoology). "We do not consider it desirable", says the Sub-Committee, "that this department [*i.e.* Archæology], which is engaged in work of considerable national importance, should be crippled." No plea of economic advantage is put forward; the Sub-Committee can, it appears, look on intellectual activities as ends in themselves, not merely as means to some material end. The claim of zoology is doubly strong; even were there no economic advantage, the Sub-Committee might well be asked to consider the works of Nature as being equally worthy of study with the works of man, and the wonderful Indian fauna as, equally with the archæological monuments, "of considerable national importance".

Upwards and Downwards in the Calculus.

Advanced Calculus: a Sequel to An Elementary Treatise on the Calculus. By the late Prof. George A. Gibson. Pp. xvii+510. (London: Macmillan and Co., Ltd., 1931.) 20*s.* net.

THE late Prof. Gibson's "Elementary Treatise on the Calculus" won the admiration of scrupulous teachers for a carefulness far in excess of what was thought adequate thirty years ago in a first course on the subject. After his resignation in 1927, Prof. Gibson prepared a sequel, of which with surprising energy he completed the manuscript within two years. At the time of his death the book was in the press and he had revised three-quarters of the proofs; Prof. MacRobert accepted the responsibility of producing the volume, and his editorial work has been done well.

Education in the calculus, as in every branch of mathematics, begins in the middle. The contents of this "Advanced Calculus" are outlined by the editor as follows:

> "The treatise begins with Dedekind's theory of irrational numbers; then follow discussions of bounded sets, sequences, limits, and differentiation of functions of one variable and of functions of several variables. Chapter v. deals with existence theorems for implicit functions and with the theory of Jacobians. Three further chapters contain accounts of infinite series, complex functions of a real variable, Lagrange's expansion, maxima and minima, infinite products, and Gamma Functions.
>
> "The integration of bounded functions forms the subject of Chapter ix.; next come expositions of curvilinear integrals, multiple integrals, and surface integrals. In Chapter xii. improper integrals . . . are introduced; and the two succeeding chapters are concerned with improper double integrals. The book closes with a chapter on the applications of the theory to the integration of series and to the Gamma Function."

Thus the title is somewhat misleading. On one hand, the volume does not touch on Fourier series or on the calculus of variations; on the other, it includes a study of first principles such as we regard as forming an introduction to analysis. It might seem that it has only to be combined with treatises on the theory of functions of a complex variable and on differential equations to provide a course truer to life than those to which we are accustomed, since in fact an English student has always some practical familiarity with the processes and applications of the calculus and with the algebra of complex numbers before he opens the works of Hardy, Goursat, or Jordan.

Unfortunately, the volume is not well suited to a place in such a scheme, for two reasons. First, there is an avoidance of the complex variable which, quite different from tacit reliance on treatment elsewhere, can only be described as morbid. All the work on series, even on power series, is subject to this criticism, and the result is that when occasionally the complex variable is admitted, some of the reasoning which is meant to be complete in itself is invalid. For example, there is no proof that an absolutely convergent series can be deranged if the terms are complex, since the only proof given for real terms involves the sums of the positive and the negative terms; the paragraph headed "Derangement of a Series" concerns double series, and while it is true that for the theorem of this paragraph " the proof for complex terms is the same as when the terms are real", this proof depends on the corresponding theorem for single series.

Secondly, the account of first principles is not wholly satisfactory. Extremely lucid in places, it is marred by locutions of a kind which can only cause the student unnecessary mistrust of his own judgment; for example, " ξ is said to be . . . interior to the interval (a, b) if there are numbers x', x'' such that $a<x'<\xi<x''<b$ ". In the treatment of exponentiation with an irrational index ξ, nothing but a tradition apparently invulnerable can account for the use of an arbitrary sequence tending to ξ, with the complication of proving that the number determined is independent of the sequence; the better the reader has understood what has gone before, the more puzzled he will be that the number required is not defined immediately as a bound. On the other hand, the theorem that for any integral value of n, nth powers are everywhere dense among the rationals, is not so trivial that it can fairly be taken for granted, and certainly an argument to which this theorem is essential is not " merely a repetition of the process " by which the product of two real numbers is shown to be definable. The discussion of the Riemann integral by Darboux's method is clear, and for the simple integral is satisfactory; in dealing with several variables, some fundamental topological difficulties must be shirked, but the possibility that a region connected in a rectangle may give rise to groups of regions in each quarter when the rectangle is subdivided ought not to be ignored. It is to be added that no other integral than the Riemann integral is introduced.

Development of technique is, however, a different task from stabilisation of foundations; it proceeds at a different pace and lays a different stress. In this field there could not be a better guide than Prof. Gibson. It was a habit of Herman's to protest to his pupils that they were slavishly dependent on contour integration: "I have never seen the integral yet that I couldn't do as easily without a contour as with one, and there are plenty for which Cauchy's theorem is no use at all". I am afraid that most of us took this wholesome corrective with more salt than it needed. The range of Prof. Gibson's examples of definite integrals is astonishing, and should convince the student that it is worth while to be as familiar with the methods explained as with those which are deliberately avoided.

The part of this volume which is covered by the title is valuable, and fills admirably a place not occupied by any other English work. If there are slips, these are easily corrected, and a blunder at the foot of p. 118 is too grotesque to mislead anybody. The treatise will be of great service to teachers and students of analysis. E. H. N.

(1) THE publication of the lectures delivered at Cornell by the non-resident professors (of whom two are appointed in each year) has the effect in many cases of bringing a number of distinct and

independent monographs within the covers of a single book. This is perhaps inevitable as a method of providing a permanent souvenir of the lectures, but from the point of view of the reader and purchaser this system of grouping is not always ideal. Thus the present volume contains, in addition to an introductory lecture and an excellent portrait of the lecturer, reports of three courses of lectures, which have no obvious relationship to one another except that they deal with subjects which have all been studied in the laboratory at Groningen.

The principal interest of the first course on " Spatial Arrangements of Atomic Systems and Optical Activity " is to be found in the evidence that, after spending a decade in plotting graphs in illustration of the Cotton phenomenon, the author is now becoming interested in the mathematical form of his curves of rotatory dispersion, and in the circular dichroism which gives rise to them. It is a curious coincidence that an attempt to solve this problem was being made by Dr. Werner Kuhn in Heidelberg at the time when these lectures were being delivered, and that a provisional solution has been given by Kuhn and Braun whilst the lectures were being prepared for publication.

The second course of lectures, on " Methods, Results and Problems of Precise Measurements at High Temperatures ", describes the work that has been done in the author's laboratory in measuring the surface tension of liquids between − 80° and 1625°, with similar determinations of density, viscosity, electrical conductivity, and specific heat. In the same way, the closing lectures on " The Constitution and Structure of Ultramarines " describe the work which was summarised at the recent discussion of the Faraday Society on " X-rays and Molecular Structure ".

The collection of so much work into a single volume, as an alternative to a disperse system of serial publication, will be welcomed by many readers, and, apart from the pleasure given by a continuous and readable narrative, the book will be of real service as a guide to the hitherto uncollected works of an author who has been prolific in exact research in more than one important field.

(2) In view of the fact that at least three books on the determination of hydrogen ions are already available, it was not obvious, from an inspection of the cover and title, why this volume should have been produced. The preface makes it clear, however, that the standard works on the subject have proved too difficult for use in the many industries in which strict control of acidity has been found to be essential. The present volume was therefore written to supply the " needs of the busy worker on strange ground ", who is more interested in the practical applications of this type of measurement than in its theoretical basis.

The book begins badly by asserting that " acidity and alkalinity are not opposites, but merely represent stages or levels on a common scale "; and it is equally at fault in asserting that " a base is dissociated in solution into negatively-charged hydroxyl ions and a positively-charged residue ", since this definition implies that aniline must not be described as a base except when it acts in the presence of water. It is not surprising that a definition such as this is followed by a confession that " it is difficult to distinguish between an alkali and a base ". This confusion is confirmed and increased by a further statement that " The former term is used for soluble hydroxides of metals or of ammonia, whilst a base is essentially a salt-forming substance which yields OH′ ions in solution ". The author's incidental references to Debye and Hückel and to " E. H. Armstrong " are as unsatisfying as his definitions of acids and bases, and have evidently been added to satisfy the author's conscience, rather than for the sake of the busy worker, since they introduce an element of complexity, which might have been avoided by one who was himself more at home amongst modern developments in these directions.

In spite of the difficulties besetting so many writers on the theory of solutions at the present time, which the author himself has not been able to avoid, his presentation of the subject is attractive and appears likely to prove of real value to workers for whom the existing monographs are perhaps too formidable and almost certainly too expensive. Its utility is increased considerably by a section in which the methods and technique applicable to particular cases are described. Mention must also be made of the ample supply of references to original literature, which in this particular section occupy four pages of the text, and of seven pages of tabulated data which are collected at the end of the book.

(3) It is interesting to find that it is still possible to produce a book setting forth the " inadequacy of the dissociation theory " of solution and setting up the " association theory " as an adequate substitute. It is, indeed, not difficult to discover data which cannot be predicted by the theory of electrolytic dissociation, either as enunciated by Arrhenius or as developed by Debye and Hückel; but the association theory owes its popularity, not merely to the elements of truth which it obviously contains, but even more clearly to the fact that

it makes no predictions, and is sufficiently vague and intangible to be invoked as an explanation of almost any conceivable series of data. Thus it can be used to ' explain ' a contraction or an expansion, an increase or a decrease of conductivity, or a change of optical rotatory power of any and every type, but only *after* the relevant data have been established.

The author is very persistent in the claims which he makes on these lines on behalf of the theory " that in solution the solutes form compounds with solvent in proportion equal to the dilution ", which is really a reversion to the views of Berthollet rather than of Mendeléeff or Pickering. His comments are, however, destructive rather than constructive, and the limitations of his point of view are indicated by the fact that no reference is made either to Debye or to the Braggs, and that the index does not include any reference either to the quantum theory or to the electronic theory of valency. The book contains a large number of misprints, a few of which have been corrected in a table of errata; it is copiously supplied with references and contains many tables of experimental data.

(4-7) It is only necessary to put on record the fact that the " Practical Physical Chemistry " of Fajans and Wüst, which was reviewed in these columns (NATURE, March 8, p. 380; 1930), has been translated into English, with a preface by Prof. Donnan, in which he states that the translation will be used in his own laboratory. The book is nearly three times as big as the original German version, but this is due merely to the use of a different kind of paper, since the number of pages is very nearly the same. We may also welcome, without comment, the appearance of a second English edition of Prof. Kruyt's excellent textbook on " Colloids ", and note the appearance of further instalments of Kopaczewski's book on " Biocolloidologie " and of Jellinek's " Lehrbuch ", of which earlier portions have already been reviewed.

"Of composts shall the Muse disdain to sing?"*

The Waste Products of Agriculture: their Utilization as Humus. By Albert Howard and Yeshwant D. Wad. Pp. xiv + 167 + 14 plates. (London: Oxford University Press, 1931.) 7*s.* 6*d.* net.

SWIFT decay, undeniably manifesting itself in many parts of rural England, has evoked divers proposals for changes in farming policy. ' Extensive ' methods, in imitation of the large scale, fully mechanised corn-growing of certain overseas countries, have been widely advocated. But the past year or two has seen, also, the growth of an entirely contrary opinion. This holds that common sense or shattering competition is bound shortly to restrict wheat and the other great crops to those areas which, biologically and economically, offer them the best environment; and in these chosen areas, crop production will be intensive. So far it is only in America that this view has been publicly ventilated, and the volume in which Howard and his collaborator range themselves solidly on the side of ' high farming ', and propound a basis for it, thus makes a timely appearance. For these authors the road to success is systematic conversion of agricultural waste products into humus. But, condemning separate methods such as green manuring, making manure in yards, etc., they insist on a single process whereby all available kinds of waste are converted together into a finely divided end product. The method, as they say, is a highly developed form of ' composting '.

The early chapters are occupied in making out the case for the authors' contention that " humus provides the very basis of successful soil management and agricultural practice ". They open with a brief but critical survey of the farming systems of the world. In the policies of America and other agriculturally comparable areas they perceive the need for a great change-over which will concentrate effort on ever-increasing yield per acre rather than upon yield per man. They suggest that " a portion of the impoverished prairie lands should go back to grass "; and they charge Europe, and all other areas which have a highly developed agriculture, with an error of the first magnitude. " To supply the large quantities of combined nitrogen needed [by land from which virgin fertility has been withdrawn] all possible sources except the right one—the systematic conversion of the waste products of agriculture into humus—have one after another been utilised; guano . . . nitrate of soda . . . synthetic compounds. . . ." Cultivators in the east, desperately in need of combined nitrogen for the betterment of their humble crops, cannot afford to buy it. But, having cheap labour and an abundance of vegetable and other waste, they can be taught how to become their own " chemical manufacturers ".

Drawing mainly on the studies of Waksman and others on organic matter in the soil, strong emphasis is laid on the importance of humus as a habitat for soil micro-organisms and on the dual nature of the utilisation of waste products. Humus formation (by bacterial and fungoid action) must be regarded as quite distinct from the utilisation of formed humus by the plant. Moreover, the requirements of the first phase—the preparation of humus and its incorporation into the soil mass—are " so intensive that if the process takes place in the soil itself, it is certain to interfere with the development of the crop ". From this point of view, therefore, most of the customary methods of making humus, and particularly green manuring, are fundamentally wrong. The reader may find in this phase of the argument an over-insistence upon the importance of combined nitrogen, to the neglect of considerations of soil texture. But he will find a very interesting case for the 'single source' method of supplying organic material to the soil, with the details of which the greater part of the volume is concerned.

---

* "The Sugar Cane", by James Grainger, M.D., 1764.

One may doubt whether a method involving many operations, sound judgment, organisation, and careful control can be operated by native cultivators without somewhat close supervision. Experience alone can test this point, but the Indore method has, at any rate, been worked out in full detail and with much ingenuity. The raw material comprises soiled cattle bedding, cotton stalks, cane trash, weeds, fallen leaves, green manure crops (cut and carted off), urine, wood ashes, etc. There is nothing casual in providing or assembling this waste; for all relevant operations, for example, the method of littering the working cattle, are so planned as to fit into the general scheme of " humus manufacture ". Fermentation, effected in pits, is initiated by addition of a simply made " fungus culture ". Three turnings of the material in the pit are needed, and from start to finish of the process occupies about ninety days. With suitable modifications for monsoon weather, etc., manufacturing is kept in progress throughout the year. Prolonged experiment has furnished interesting data as to the influence of water content and temperature of the pit, the optimum carbon-nitrogen ratio of the raw material, the phases of fermentation, and the manurial value of the final product.

In the chapter describing working details, the practically-minded reader will scarcely pass by a single page without commenting on the heaviness of labour requirements. He may feel, too, that even mechanisation, which the authors point to, may never avail to meet the difficulties where labour is costly. But the authors have an answer—perhaps the only answer that could be given in such a case. They have perfected the process on the Indore station and have given full details of work, of raw materials, of the relation of head of working cattle to land area, amount of waste, and output of manurial product.

There can be no doubt about the novelty of these proposals, their boldness, their ingenuity, and the interest they are certain to arouse. This is far more than a controlled method of composting; it is, rather, a new system of farming designed upon a basis of composting. As to possible difficulties of application even in tropical countries, there is, equally, no doubt. But, against this, it must be remembered that in boldness the proposals are matched by the aim, which is to make intensive cultivation possible without the use of purchased nitrogenous fertilisers.

F. L. Engledow.

Short Reviews.

(1) *The Printing of Textiles.* By Rego Capey. Pp. x + 138 + 29 plates. (London: Chapman and Hall, Ltd., 1930.) 13*s.* 6*d.* net.

(2) *Textiles on Test: a Study for Distributor and Consumer of the Wearing and Washing Properties of Fabrics and Garments.* By J. Guilfoyle Williams. Pp. viii + 194 + 40 plates. (London: Chapman and Hall, Ltd., 1931.) 7*s.* 6*d.* net.

(3) *Soies artificielles et matières plastiques.* Par Robert Gabillion. (Collection Armand Colin: Section de Chimie, No. 129.) Pp. 204. (Paris: Armand Colin, 1931.) 10·50 francs.

(1) It needs technical specialists to do justice to such subjects as these three books take into consideration. That the authors are well equipped for their several tasks is quite evident. But with due respect to Mr. Capey, exception must be taken to the association of a fifth century B.C. fabric with the subject of the Annunciation; nor does this seem to be a slip for 'A.D.' He is doubtless correct in stating that textile printing was probably independently developed in many countries; the diagrams and illustrations endeavour to lighten a dull text.

(2) Mr. Williams, in a companion volume, shows how to make such a highly technical subject attractive reading, irrespective of the numerous illustrations the book contains. His extensive knowledge is placed generously at the reader's service.

(3) M. Gabillion discourses with insight upon the subject of artificial silks and plastic materials. *Inter alia*, the pages dealing with the introduction and development of Lincrusta Walton and linoleums are not the least interesting of the two hundred pages to which the book extends. It is eminently practical, proving more readable than Mr. Capey's, though lacking the attraction attached to Mr. Williams' treatise, to which Mr. Gordon Selfridge supplies a foreword.

P. L. M.

Non-Metallic Inclusions in Iron and Steel. By Dr. Carl Benedicks and Helge Löfquist. Pp. xi + 311 + 44 plates. (London: Chapman and Hall, Ltd., 1930.) 30*s.* net.

THE useful properties of steel, especially of the higher qualities of steel, depend in large measure on the degree of freedom from non-metallic inclusions. These inclusions, by providing regions of concentration of stress, lower the resistance to fatigue, whilst they also influence the behaviour of the steel towards corrosive agents. Improvements in the manufacture of steel are largely directed towards their elimination, and for the success of such improvements a knowledge of the composition and mode of origin of inclusions is essential. The chemistry of the bath reactions in the steel furnace, by which most of them are formed, is complex, and the authors of this work have had a difficult task in their critical examination of the data. Their presentation is clear and systematic, and for the first time a mass of detailed information concerning inclusions in steel is brought together and discussed in the light of physical chemistry. Metallurgists will not all agree with some of the hypothetical equilibrium diagrams, but these furnish at least a basis for discussion.

The volume is well printed and abundantly illustrated. The micrographic and analytical methods for the identification of inclusions are described, and a general account of ingot structure is included. The practical metallurgist will also find the discussion of the means adopted to lessen the quantity of inclusions, or to disperse them in the least harmful way, an interesting study.

Nutrition and Food Chemistry. By Barnard S. Bronson. Pp. viii + 467. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 18*s.* 6*d.* net.

THE author has attempted a presentation of the scientific principles of nutrition in simple form and suitable for students with little foundation in physiology and none in organic chemistry. The book includes the elements of digestion and metabolism, with details of the composition of many foods. Data are supplied from which it is possible to construct diet sheets and to estimate the suitability of common diets, but for useful dietaries the reader must consult books on dietetics.

The work is based on American practice, and includes descriptions of methods of treating or manufacturing common foodstuffs, as well as of the standards with which various foods must comply: thus, the pasteurisation of milk, the manufacture of ice-cream, and the baking of bread are described, and standards for milk and eggs are given in detail. Although certain portions are not applicable to conditions in Great Britain, the tables of analyses will be extremely useful to all those who wish to know the exact composition of any particular diet: this applies especially to research workers, since unsuspected impurities in a purified diet may markedly affect its nutritive value. For these, the appendices on the vitamin, iron, and copper contents of foods should prove of value.

The work as a whole appears to be rather advanced for elementary students, although the earlier chapters on digestion and metabolism might be read with profit: the later appear more suitable for the specialist.

The Theory of Ruled Surfaces. By W. L. Edge. Pp. ix + 324. (Cambridge: At the University Press, 1931.) 20*s.* net.

THE general type of ruled surface of the fourth order was mentioned by Chasles in 1861. In 1864 and 1868 these surfaces were studied and classified, though not quite completely, by Cayley, who obtained his different types by means of directing curves and gave algebraic equations for them. The complete classification was first given by Cremona (1868), who used the method of correspondence between two curves. Ruled surfaces of the fifth order were classified by means of their double curves by Schwarz in 1867.

Mr. Edge gives an account of this work and supplements it by his own researches, which include what appears to be the first serious attempt to enumerate the ruled surfaces of the sixth order. He employs two powerful general methods, considering the surfaces as curves in a five-dimensional space, and projecting from space of even higher dimensions. The first chapter contains an account of the principle of correspondence and of other ideas fundamental in modern algebraic geometry. There is no other book easily accessible to English readers where these are explained and applied so extensively. The properties of the ruled surfaces of orders four, five, and six are collected in tables, but there is, unfortunately, no index.

H. T. H. P.

Organic Syntheses: an Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Editorial Board: Carl S. Marvel, Editor-in-Chief; Roger Adams, W. H. Carothers, H. T. Clarke, J. B. Conant, Henry Gilman, C. R. Noller, F. C. Whitmore, C. F. H. Allen. Vol. 11. Pp. vii + 106. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1931.) 8*s.* 6*d.* net.

THIS volume contains particulars of thirty-one preparations. Of the contributors, fourteen are from the United States, two from Germany, and one each from Canada, India, and Austria. Among the interesting preparations are itaconic anhydride and acid (from citric acid), citraconic anhydride and acid (from itaconic anhydride), mesaconic acid (from citraconic anhydride), cyanogen bromide (from sodium cyanide and bromine), ethyl pimelate (from salicylic acid), fumaric acid (in 58 per cent yield from technical furfural), and thiobenzophenone (from benzophenone dichloride and sodium hydrosulphide). The conversion of acrolein into *dl*-glyceric aldehyde in 11 per cent yield is described through the following intermediates: β-chloro propionaldehyde acetal, acrolein acetal, and *dl*-glyceric aldehyde acetal. The revised collection of preparations contained in the first nine volumes of this valuable series is to appear soon.

J. R.

A Century of Geology.*

By Prof. J. W. Gregory, F.R.S.

THE geological problems of special interest in 1831 are shown by the contributions prepared at the request of the British Association, with first amongst them Conybeare's "Report on the Progress, Actual State, and Ulterior Prospects of Geological Science". His report summarised the position in general stratigraphy, which was still based on two divisions—the primary and the secondary. The secondary group, thanks to William Smith, had been classified into four systems—the Carboniferous including the Old Red Sandstone, the New Red Sandstone, the Oolitic, and the Cretaceous. All below the Old Red Sandstone was left as the primitive and transition series. The pre-Carboniferous and post-Cretaceous beds were still in confusion, but Conybeare's section from the north of Scotland to the Adriatic near Venice shows that the general succession had been established from the Tertiary to the Carboniferous and Old Red Sandstone.

The first great stratigraphical advance after 1831 was Lyell's classification in 1833 of the post-Cretaceous strata. Lyell's achievement was followed by the foundation of the Silurian system by Murchison Murchison, in 1834, showed that the 'Upper Grauwacke Series' included four fossiliferous series, which in 1835 he grouped as Silurian. Sedgwick, a month later, in a communication to the Association at its Dublin meeting, founded the Cambrian system for the fossiliferous rocks below the Llandeilo and the schists of Anglesey and Carnarvonshire.

The fundamental advance in geology in the decade beginning 1830 was Lyell's demonstration of the uniformity of geological dynamics. The first volume of his "Principles" was published in 1830, and Murchison hailed it as "beginning to unfold the true papyri of geological history".

A different estimate was expressed by Adam Sedgwick, then the leader of British geology, who declared that Lyell's championship of uniformitarianism violated sound reasoning on geological phenomena, and that

> "warped by his hypothesis . . . in the language of an advocate, he sometimes forgets the character of an historian". According to Sedgwick, if Lyell's views of the uniform order of physical events were correct, "the earth's surface ought to present an indefinite succession of similar phenomena. But as far as I have consulted the book of nature, I would invert the negative in this proposition, and affirm that the earth's surface presents a definite succession of dissimilar phenomena. If this be true, and we are all agreed that it is, . . . then 'the undeviating uniformity of secondary causes', 'the uniform order of physical events', 'the invariable constancy in the order of nature', and other phrases of like kind, are to me, as far as regards the phenomena of geology, words almost without meaning. They may serve to enunciate the propositions of an hypothesis; but they do not describe the true order of nature."

Sedgwick agreed with Brongniart that the geological and historical periods were essentially distinct; and he remarked regarding the recent appearance of man, "were there no other zoological fact in secondary geology, I should consider this, by itself, as absolutely subversive of the first principles of the Huttonian hypothesis".

Murchison, on the contrary, held that Lyell's demonstration of the unbroken transition between the Pliocene and post-Pliocene had completely swept away the arbitrary demarcation between "what had been termed the ancient and existing orders of nature".

The geologists of 1831 worked under the handicap of three fundamental uncertainties. The problem of sea-level so exercised the Geological Committee in 1831, that it asked Robert Stevenson—the authority on coastal engineering and grandfather of R. L. Stevenson—to report upon the erosion of the English coast and "the permanence of sea-level". He replied that he had little to add to his previous papers (1816 and 1820) The variability in sea-level is of perennial interest as many issues depend upon it. The test case about 1830 was that of the Baltic. Celsius in the eighteenth century had remarked that the Baltic was receding along the Swedish coast; but, as the German coast had undergone no such change since Roman times, the Swedish evidence was doubted. Leopold von Buch reconciled the observations by the hypothesis that the Swedish coast was rising about a pivot, while the German coast remained stationary. The facts were reaffirmed by a joint inquiry of the Swedish Academy of Sciences and the Russian Ministry of Marine; but the rise of the land was rejected by Lyell. He attributed the recession of the sea to the accumulation of sediment and the wind.

Lyell fortunately examined the evidence for himself, and in a paper read to the Association in 1834, accepted von Buch's conclusion that parts of the Baltic coast are rising two to three feet in a century, while other parts are stationary.

The Baltic, therefore, gives convincing testimony of the mobility of the land, which is accepted in an extreme form by some champions of isostasy. That principle was put forward from the geological evidence that the rate of the accumulation of sediments so often coincides with the rate of subsidence that the two processes must be dependent, the weight of the sediment being the cause of the subsidence. The correlative, that the unloading of an area by denudation causes its uplift, was advanced by Clarence King (1876). This cause of the rise and fall of land was maintained by Airy and Pratt, and was supported by the gravity surveys by Hayford, Hecker, and Duffield. The relief of the earth was attributed to the differences in the density of the crust, and therefore the subsidence of the crust to form oceanic basins, and its uplift into continental masses from oceanic depths would be both impossible. That theory was of service as a reaction against the lightly assumed interchange, as pictured by Tennyson, of roaring streets and central seas; but the form of isostasy that represents the earth's major relief as determined by the perfect hydrostatic equilibrium of the crust is opposed to weighty evidence.

---

* From the presidential address, entitled "Problems of Geology Contemporary with the British Association", to Section C (Geology) of the British Association, delivered in London on Sept. 24.

The mathematical data for the permanence of the ocean basins seem unreliable. That the ocean floors consist of a continuous sheet of heavy material (sima) was supported by gravity determinations; but the calculations are based on the assumption that the sea surface stands at the spheroid of reference.

That some parts of the crust are in such delicate isostatic equilibrium that the surface rises when material is removed by denudation and sinks when loaded with more sediment is well established; but other parts of the surface have not this delicate poise. Faults have a downthrow of 10,000 feet, and there is no evidence that their cause was sedimentation. The dependence of subsidence and sedimentation may often be true for the geosynclines, which, owing to the rupture or instability of the crust in consequence of its deformation, are bands of long-continued weakness—or asthenostrophes (weak bands or belts).

Reluctance to accept the hydrostatic equilibrium of all parts of the crust is not due to prejudice against isostasy. But its extension to the whole surface of the earth and the claim that it proves the subsidence of an area to an oceanic depth to be a physical impossibility are contradicted by geological evidence, which appears more reliable than calculations based on uncertain assumptions.

THE FIXITY OF SPECIES.

The second hindrance to geological progress in 1831 was the belief in the fixity and special creation of species, which was then entrenched by theological authority.

The fixity of species had been attacked by Lamarck, but his view of the evolution of one species into another was emphatically rejected by British authorities. Buckland, who was the president of the Association at its first full meeting, denied that he was in any way disposed to favour Lamarck's theory of "the derivation of existing species from preceding species by successive Transmutations of one form of organisation into another form, independent of the influence of any creative Agent". Sedgwick repudiated "the doctrines of spontaneous generation and transmutation of species with all their train of monstrous consequences". The latter doctrine, with all its momentous consequences, was added to the principles of geology by a recruit of 1831. Early that year, Charles Darwin began the study of geology, and on his return from his first long geological excursion, which he made with Sedgwick in North Wales, received the invitation to go as naturalist with the *Beagle*. He sailed in her from Plymouth in December 1831.

Darwin's work on the voyage was mainly concerned with volcanic rocks, with gravity differentiation in molten rocks, with uplifts accompanying earthquakes, and with the evidence of widespread areas of subsidence and uplift as proved by his luminous and now firmly established theory of coral islands. His work on crustal movements was of primary importance; but by his doctrine of evolution by natural selection, he was the most potent influence on the thought of the Victorian era. According to the general interpretation of the geological record, evolution has been mainly controlled by the environment, and has proceeded slowly during the long periods of relative quiescence and more quickly when the tumultuous heaving of the crust produced relatively rapid changes in the physical conditions, as in the depth of the sea, in the temperature of sea-water, and in climate owing to the altered distribution of land and water and relief of the land.

The influence of Darwin on the whole philosophy of geology was so helpful that he was the dominant factor in its progress during the second quarter-century of the Association's work.

The geological point of view of the day as regards the relations of geology and theology was shown in Buckland's "Bridgewater Treatise" (1836, p. 414). He argued that zoophytes show such perfect unity of design that we can find no explanation of such otherwise mysterious uniformity than by referring it to the agency of one and the same creative intelligence. He extended this argument to the whole organic world. The persistence of the same structural plans and the absence of those freak animals which might be expected if animals had arisen by special creation —instead of being regarded as evidence of evolution—was claimed by Buckland as proof of special creation by one Creator.

Buckland, though he defended the creation of man at 4004 B.C., and declared in regard to the six days of creation, "I see no reason for extending the length of any of these beyond a natural day", was, nevertheless, too heterodox for some members of the Association. His view that the earth is indefinitely older than the creation of man was vehemently attacked by Dean Cockburn, the Dean of York, in 1838, and at the meeting of the Association there in 1844. It was not until about thirty years later that geology secured the independence claimed in 1832 by its doughty champion, Murchison, in his assertion of the "entire disconnexion of our science with the inspired writings".

THE ORIGIN OF ORE-DEPOSITS.

The third geological problem to which the Association directed attention was the nature of ore-deposits.

The classification of mineral veins in 1791 by Werner attributed them to the filling of fissures from solutions. Hutton, in 1795, declared the deposition of native metals from solution a "physical impossibility", and that sulphide ores could only be formed at high temperatures. In 1831, in reaction from such speculations as to genesis, the standard classifications relied on the form of the deposits; Taylor rejected the formation of lodes by igneous injection and attributed ordinary ores to sublimation. As many mineral veins were too wide to have been formed by the infilling of open fissures, the electric deposition of the ores was advocated by R. W. Fox in papers to the Association. Ami Boué, in 1822 and 1829, supported the general association of mineral veins and igneous rocks, and A. L. Necker also urged, despite a few apparent exceptions, the general "connexion of igneous with metalliferous deposits".

In 1835 the main alternative explanation—the connexion of mineral veins with great fractures—was put forward by J. Fournet. He assigned the minor veins to the filling of shrinkage cracks and small faults, and the veins of most economic value, to deposition along major faults.

That the ores along these fractures were due to rising waters was rendered the more probable by the paper contributed by C. G. B. Daubeny at the 1836 meeting on "Mineral and Thermal Waters". Meanwhile, the theory that ores were derived from waters percolating through the rocks beside the veins had been revived by Bischof (1847), but was generally rejected until Forchhammer and Sandberger found particles of the ordinary ore metals in all kinds of ancient rocks.

The ascensionist was then replaced by the lateral secretion theory, which was dominant for twenty years, until in 1893 the deep-seated source of most ores was advocated by Posepny. An intermediate view, advocated by Kemp, redirected attention to the general association of mineral veins with igneous rocks; and the view that the constituents of the lodes are derived from igneous rocks is perhaps still the generally accepted theory. There are serious objections to it: for though many metals occur in the igneous rocks, the quantity appears insufficient to have furnished the lodes. Many of the claims for the presence of such metals as primary constituents of igneous rocks are invalid. The distribution of ores indicates their derivation from a layer below the igneous rocks.

The deep-seated source of ore-deposits bears on the geology of the inner earth, which was exercising geologists in 1831, when amongst subjects recommended for examination were the "accurate examination of the conclusions deducible from the known density of the earth, as to the solid structure and composition of its interior", and "the examination of the visible disk of the moon, with the view of extending our general knowledge of volcanic forces".

When the efforts to correlate the main relief of the earth were resumed, the most stimulating worker was Élie de Beaumont. His correlation of mountain chains was based on the view that the interior of the earth is slowly cooling and contracting so that the outer shell undergoes alternate deformation and recovery of the spheroidal form. He concluded that these crustal movements account for the mountain ranges and main relief of the earth. He realised that the crust is a unit which is affected as a whole by each of the orogenic episodes which upheaved mountain systems at the same date in even distant parts of the earth. He held that fold-mountain chains of the same orogeny are recognisable by their trend, and classified the mountains of Europe into four systems, each with a characteristic trend. As the trends were determined by the fracture of a spherical or subspherical shell, he considered that they would be on a regular geometrical pattern.

Élie de Beaumont's views attracted earnest attention, and at the first meeting of the Association Sedgwick and Conybeare were asked to report whether his maxim that mountain ranges with the same trend were of the same age holds true for the British Isles. Sedgwick replied that the older British strata are in strict accordance with Élie de Beaumont's theory, and expressed enthusiastic approval of it in his presidential address to the Geological Society. He declared—

> "that the system of M. Élie de Beaumont is directly opposed to a fundamental principle vindicated by Mr. Lyell cannot admit of doubt. And I have decided, to the best of my judgment, in favour of the former author, because his conclusions are not based upon any *a priori* reasoning, but on the evidence of facts; and also because, in part, they are in accordance with my own observations."

Conybeare was more critical of Élie de Beaumont's theory. He objected to describing the Urals and the American Cordillera as parallel, and held that the correlation of English folds by parallelism is unsatisfactory.

Élie de Beaumont's work laid the foundations of the modern study of the general plan of the earth. His fundamental principles were that the main movements in the earth's crust are due to its compression owing to the shrinkage of the internal mass, and that the collapse of the crust determines the main features in the relief of the globe. The shrinkage is probably due more to closer packing of the constituents than to cooling. That the main folding of the crust has been due to compression that at first acted on all parts of the earth, and later was confined to special belts, seems one of the most certain of geological facts.

Élie de Beaumont unfortunately adopted as the basis of his fold-and-fracture pattern the pentagonal network, which had to him the recommendation of its possession of a high degree of symmetry. The most obvious fact in the map of the world is that it has no such highly developed symmetry.

I endeavoured to show in 1899 that Lowthian Green's theory agrees with the existing distribution of ocean and continent, and with geological history, as it explains the alternation of the slow subsidence of the ocean floors and of crustal storms during which fold-mountain chains are raised by lateral compression; it also explains the alternate emergence of the lands as the ocean basins are enlarged by the sinking of their floors and submergence of the lands by the world-wide advance of the sea due to the shallowing of the oceans when the spheroidal form is recovered after the tetrahedral deformation has exceeded the stability of the crust.

Élie de Beaumont's elaborate classification of mountains has collapsed; for although the foundations were sound, his superstructure was not. Knowledge of the structure of mountain chains was then inadequate and much of it was erroneous. Beaumont's conception of mountains was defective; he regarded them as symmetrical ridges, and he failed to appreciate the contribution to the Association in 1842 by Henry Darwin Rogers, which laid the foundation of the modern theory of mountain formation. In 1842 Rogers read to the Association his joint paper with his brother, W. B. Rogers, "On the Physical Structure of the Appalachian Chain, as exemplifying the Laws which have regulated the elevation of great Mountain Chains generally". The Rogers considered the facts at variance with Élie de Beaumont's hypothesis. They explained mountain chains as waves in the crust due to a broad belt being pushed forward with accompanying asymmetric folding, overfolding, and inversion.

Suess showed that the existing physiography of Europe was mainly due to the Alpine System—including the Pyrenees, Alps, Carpathians, and Balkans—having been pushed northward against resistant masses which threw back the waves like forelands along a coast. Suess had the advantage over the geologists of the 'thirties of more certain petrology. They still worried over the igneous origin of granite, and even a decade later were at issue as to whether granite had been injected as a molten mass at a high temperature, or was due to aqueo-igneous action at a low temperature.

A great advance in the interpretation of the igneous and metamorphic rocks followed Sorby's application to them of the microscopic study of transparent sections. He announced its illuminating results to the Association at Leeds in 1858, showing that the crystals and bubbles in the fluid cavities in granite prove its deep-seated origin, and that the Vesuvian lavas demonstrate that the sequence of minerals in igneous rocks is determined not by their fusibility but by their order of crystallisation out of a cooling solution.

The interpretation of mountain structure had an important reaction on stratigraphy. Suess's study of world geology led to the recognition that some encroachments of the sea upon the land were world-wide; he called them the marine transgressions, and explained them by the reduction of the ocean basins

Many cases of the rise of the sea surface may be due to changes in the ocean basins and not to a vertical uplift of the land. Suess regarded some high-level horizontal beds as left in their original position by the down-sagging of the crust elsewhere. He was so impressed by the predominance of downward movements in sunklands, rift-valleys, and oceanic deeps, and by the absence of any mechanism which he regarded as adequate for widespread horizontal uplifts, that he considered all vertical regional movements must be downward. In this he went too far; but that the land sometimes emerges owing to lowering of the sea surface, and at others is submerged by the rise of the sea-level, is now universally admitted.

In 1831 Conybeare dismissed the stratigraphical principle, "Werner's dogma of Universal Formations", as he held that in distant lands corresponding formations are not synchronous. This idea, also adopted by H. D. Rogers in a paper to the Association in 1834, was a forecast of Huxley's doctrine of homotaxis, which is less important now that as much time is available as the greediest geologist can desire.

The zonal divisions, however, are being found less universal than had been thought. The view of Oppel (1856, etc.) that ammonite zones in all parts of the world follow in an identical succession, and the expectation that graptolite zones are equally regular and world-wide, have proved exaggerations; Dr. Spath has pointed out that the sequence of zonal ammonites differs in different basins. Geologists were once confident that the gaps in the geological column in Europe would be filled by discoveries elsewhere; such terms as Permo-Carboniferous, Permo-Triassic, etc., expressed the hope that the beds thus named would fill gaps in the European sequence. Most of these strata have been found to correspond in time with those known in Europe. Extra-European stratigraphy has shown the world-wide range of the geological systems.

THE GEOLOGICAL LEADERS OF THE FOUR QUARTER-CENTURIES.

My impression is that from 1830 until 1855 the true prophet of geology was Lyell, with his establishment of the mobility of the land and the uniformity of geological processes. From 1855 until 1880 the main advance was Darwin's establishment of evolution, which enabled fossils to be interpreted more intelligently and reliably. About 1880 the geologists of the United States revealed phenomena in their western mountains which showed that the yardstick reliable in north-western Europe and the Atlantic States of America was not applicable everywhere. The United States Geological Survey began its great influence about 1880. Nevertheless, despite the powerful stimulus of North America on geological thought in the third quarter of the past century, the most profound individual influence was that of E. Suess.

The last quarter-century is still too near for reliable appreciation of its achievements; but among the fundamental advances have been those revealing the structure of the inner earth, and especially the interpretation of earthquakes, in which the pioneer was John Milne. The recent study of ore-deposits confirms the evidence from earthquakes that the core of the earth is surrounded by concentric shells and that the metallic ores arise from the shell below the plutonic rocks as gases and solutions. The geology of mineral fields and the extension to most of the younger mountain ranges of the world of the thrustplanes which, though early recognised in mining, were first demonstrated in stratigraphy by Lapworth in the north-west of Scotland, have proved that fold-mountains are formed along belts of compression.

The Volta Conference at Rome.

THE second Volta Conference was held in Rome from Sunday, Oct. 11, until Saturday, Oct. 17, and was devoted to the subject of nuclear physics. The proceedings were opened on Sunday morning by a reception, at which addresses were given by the Marchese Marconi and Prof. Corbino—the Prime Minister, the Duce Mussolini, presiding. Six morning sessions and three afternoon sessions were held, during which many interesting contributions were made. A full report of these is to be published shortly by the Royal Academy of Italy.

The subject of penetrating radiation was handled by Dr. B. Rossi, and led to a very interesting discussion. It appears that we are yet a long way from understanding this phenomenon, but a variety of new methods of investigation are now being applied, which at least promise to yield important information. A considerable part of the conference was devoted to the discussion of the general applicability of our present theoretical ideas to nuclear problems, and it appeared, largely through the important contributions of Prof. N. Bohr, that we cannot expect the present quantum mechanics to apply to the nucleus without undergoing such a fundamental change that it might almost be said to involve a new mechanics, including the present quantum mechanics as a limiting case. In particular, it may be noted that it appears difficult to calculate the probabilities of occurrence of the different nuclear processes to within even an order of magnitude, so that it is quite impossible to decide whether there is or is not a discrepancy between theory and experiment in comparing such experimental results as the number of long-range α-particles and the number of quanta of the corresponding radiation emitted by the excited nucleus. The position appears to be that we should scarcely anticipate that the quantum mechanics would apply even to the α-particles in the nucleus as well as it does, and there is clear evidence that the questions connected with the electrons in the nucleus raise problems quite outside its scope.

Most of the nuclear phenomena which are open to experiment were discussed, such as the values of the nuclear moments, the artificial and natural disintegration of the elements, the excitation of nuclear γ-rays, the absorption of radiation by the nucleus, the information about the α-particle stationary states in the nucleus and their association with the γ-rays, and also the transference of energy from the excited nucleus to the electronic structure.

The general impression appeared to be that a definite stage in attacking the problem of the nucleus had already been reached in that recognised experimental methods had been adopted, and the general scope of the information they could provide was understood. The problem of the nucleus can at least be divided into several smaller problems, and to each there is now a definite approach by experimental methods.

The α-particles and the protons seem likely to be treated at least approximately by the present quantum mechanics, and it is possible that in the not far distant future a reasonable account of the behaviour of the light and heavy nuclei may be given in terms of certain experimentally defined stationary states of α-particles and protons, the existence of which may at least be made plausible by theoretical calculations based on the equilibrium of such particles inside a potential box. On the other hand, the question of the behaviour of the electrons appears to introduce problems which are not found elsewhere in physics. This point was specially emphasised in connexion with the discussion of the continuous spectrum formed by the disintegration electrons from radioactive bodies.

It would be difficult to express adequately the thanks which the delegates owe to the organisers of this conference, not only for the admirable arrangements which were made for the scientific discussions, but also for the magnificent hospitality which was shown to them. The success of this conference was largely due to the untiring efforts of Prof. O. Corbino and the secretary to the conference, Dr. E. Fermi, who managed to combine both the necessary firmness in directing the conference with the freedom which is so essential for fruitful discussion.

Radio Research in Great Britain.*

THE Report for last year of the Radio Research Board to the Committee of the Privy Council for Scientific and Industrial Research is of interest, as it marks the beginning of a new stage in the investigations. In the earlier work, apparatus and methods have been perfected so that trustworthy and consistent results can be obtained. It is now considered undesirable to proceed further in this direction. Scientific research on which future progress depends is divided into two branches. The first is the fundamental research undertaken without any immediate practical application in view. The second is to initiate experiments likely to indicate solutions of the urgent problems at present engaging the attention of radio engineers.

The Board considers that, while a proportion of the problems of fundamental research can be undertaken in the confines of a university laboratory, there are many problems that cannot be carried out in this way, as they require the co-operation o observers at great distances apart. This work is continued by the Board, although priority is given to experiments the application of which is clear. During last year, close collaboration was maintained with the radio research boards established by the governments of New Zealand and Australia. Priority is being given to the study of high frequency

* Department of Scientific and Industrial Research. Report of the Radio Research Board for the Period ended 31st December 1930. Pp. iii+90+4 plates. (London: H.M. Stationery Office, 1931.) 2s. net.

transmissions of wave-lengths less than ten metres. Much use has been made of the frequency-change method developed by Prof. E. V. Appleton for the study of the ionisation of the atmosphere and its effect on the propagation of waves. The most noteworthy advance made in the study of atmospherics during the year has been largely due to the new cathode ray oscillograph developed by Baron Manfred von Ardenne, of Berlin. By its use it was possible to photograph the wave forms of atmospherics previously observed visually.

In the frequency-change method, a small continuous change is made in the waves being generated. This produces at the receiving station a succession of interference maxima and minima due to the ground waves and the waves deviated by the upper atmosphere. It is possible to estimate from these effects the relative intensities of the ground and atmospheric waves and the angle of incidence of the latter with the ground. A comparison of the phase differences between the two sets of waves can be deduced from the interference fringes and this gives information as to the polarity of the down-coming waves. Strong experimental evidence is given of the existence of three zones of ionisation in the atmosphere. The region of ionisation which normally reflects long waves and broadcasting waves is referred to as the *E* region, while hypothetical reflecting layers above and below the *E* region are called the *F* and *D* regions respectively.

It was found that with a wave-length of 400 metres the secondary fringes were observed during the night, but that about forty minutes before sunrise their amplitude began to diminish, until only the primary fringes remained. It is concluded that with these waves the cessation of the influence of the ultra-violet radiation after sunset leads to a recombination of ions and thus causes a slow increase in the height of the equivalent layer which only ceases on the advent of sunrise. A converse effect then ensues. Observations on ‘ phase fading ’ confirm this.

The experiments show that the maximum value of the height of the ionised layer is about 126 km., but on certain nights the height remains constant at 100-110 km. The reason for this is obscure. According to the ordinary theories of radio propagation, a greater density of electrons is required to reflect or refract short waves than long waves. A study of the *F* region (the highest) is therefore more conveniently made with short waves. The experiments made with 100-metre waves confirm theory. The variations observed during the daily runs enabled the times at which the lower *E* region just began and just ceased to reflect 100-metre waves to be accurately determined. This wave-length seems to have been fortunately chosen, as it is a critical wave-length. On some days the waves penetrate the *E* region and on others they are reflected by it.

In England the equivalent average heights of the *E* and *F* (upper) regions are about 100 km. and 230 km. respectively. Using results obtained in Washington, and adopting the two-layer hypothesis, led to heights of 105 km. and 235 km., and this shows that the hypothesis is a useful one. Work on short waves (50 metres wave-length and less) is being carried out. Already evidence has been obtained bearing on the influence of magnetic storms on the ionised layer. As the problem is closely linked with the explanations of skipped distances and Stormer's theory of long retardation echoes, the results will be important. It has been found that on the occasion of a magnetic storm the ionisation of the *E* (middle) region is sufficient to reflect 50-metre waves which normally are reflected at vertical incidence. This indicates a marked increase in ionisation above the normal value. So far, the experiments on the propagation of long waves have not led to any very definite results.

Excellent results have been obtained with the development of radio frequency standards. It is clear that the various national standardising laboratories of the world are able to measure frequency to an accuracy which surpasses the constancy of the instruments used in its comparison. The agreement between the National Physical Laboratory, the Post Office, and the American Navy on the two occasions when measurements were made was to about one part in 100,000. Experiments prove that the inaccuracy of the National Physical Laboratory's measurements of frequency did not exceed three parts in a million. Much of the credit of this great achievement must be attributed to Dr. W. D. Dye.

Obituary.

PROF. J. S. C. DOUGLAS.

THE sudden death of James Sholto Cameron Douglas on Oct. 30 at Llandudno, where he had gone to recuperate after a long illness, was a very great grief to his many friends. Prof. Douglas was more closely in touch with his colleagues, both scientific and medical, than is usual in a university; for not only had he held the Joseph Hunter chair of pathology at the University of Sheffield since 1915 and been Dean of the Faculty of Medicine since 1923, but his professorship also involved him in a multitude of administrative duties, including the direction of the pathological work at the various hospitals in the city. In addition, he was always being called upon by his medical colleagues for expert advice on pathological matters. Not only did he carry out his duties with unsparing zeal, but as a most unselfish man he also responded willingly to all demands for assistance.

All this work of necessity limited Douglas's time for his own investigations. To some this was a matter of regret, especially as his published work revealed the mind of a capable investigator; but, after all, the unselfishness and high skill possessed by Douglas were of infinite value to his colleagues and other medical men of the city. His kindness and genial nature, together with the great pains he took in his work, have only increased the sense of loss felt by his colleagues. Prior to his appointment to the chair of pathology at Sheffield, Douglas was lecturer in this subject at the Universities of Birmingham (1907–11) and Manchester (1911–15).

Douglas was primarily interested in problems of immunity, but he also published some work on morbid anatomy. The most fruitful period of research included the years 1914 and 1915. In these years he published a paper on "The Cytology of the Blood in Passive Immunity", and, with the collaboration of Prof. Boycott, other papers on the composition of the tissue fluids. His other publications dealt with the adsorption of agglutinin and other immune bodies by charcoal (with Prof. Dreyer), the effect of diaphyte tubercle vaccination in guinea-pigs, relapsing pyrexia in lymphadenoma (with Prof. Arthur Hall), a study of cardiographic tracings from the base of the human heart, and the invasion of the pericardium by malignant tumours. As an investigator his work was characterised by meticulous exactness.

Douglas was born in 1879 at Leicester, the elder son of Mr. Claude Douglas, consulting surgeon to the Leicester Infirmary, and brother of Dr. C. G. Douglas, F.R.S., the distinguished Oxford physiologist. He was educated at Wyggeston Grammar School, Haileybury College, and at Christ Church, Oxford. He graduated at Oxford in 1902 and entered St. George's Hospital. After qualifying he studied abroad, mostly at Copenhagen and Dresden, as a Radcliffe travelling fellow. In 1911 he married Mary Victoire, the daughter of Mr. Richard Brice, of Burnham, Somerset. He has left behind him the best memorial any man could wish —the reputation of an able scientific worker and administrator of unlimited kindness and geniality.

THE death has occurred in Vienna of Prof. Guido Holzknecht at the age of fifty-eight years. Holzknecht was one of those medical men who took up the scientific study of X-rays soon after their discovery. He was responsible for the exploitation of X-rays especially in the field of examination by means of the fluorescent screen. In the years before the War he was perhaps more responsible than anyone for perfection in this technique, and at the Vienna General Hospital it was developed to such an extent that photography in X-ray work was of minor account. Holzknecht was a prolific writer, and there is scarcely a branch of radiology upon which he did not make important contributions. His device known as the chromoradiometer was an early attempt at measuring the doses of X-rays given to the surface of the body. Holzknecht was a big figure in the X-ray world, whether from a diagnostic or therapeutic point of view, and by his work during the last thirty years, in which, unhappily, he suffered what proved to be fatal damage to himself, he did much to put the subject on a scientific basis.

MR. EDWARD STEP, who died on Nov. 8, aged seventy-five years, was widely known in the world of entomology and natural history, and by his books was undoubtedly one of the pioneers of the popular study of Nature. He had just completed a book on "Bees, Wasps, Ants, and Allied Insects of the Wayside and Woodland", which will be published shortly. For more than fifty years Mr. Step had been a member of the South London Entomological and Natural History Society, was one of its early presidents, and was to have been president for the coming year. He was also a fellow of the Linnæan Society. In 1928 he was president of the British Empire Naturalists' Association.

WE regret to announce the following deaths:

Prof. Edward S. King, Phillips professor of astronomy in the Harvard College Observatory, known for his pioneer work in photographic photometry, on Sept. 10, aged seventy years.

Dr. John Sampson, formerly librarian in the University of Liverpool, known for his work in gypsy lore, and author of "The Dialect of the Gypsies of Wales," on Nov. 8, aged sixty-nine years.

Prof. Charlotte A. Scott, formerly professor of mathematics in Bryn Mawr College, the first woman wrangler in the University of Cambridge, on Nov. 8, aged seventy-three years.

Major U. P. Swinburne, formerly Chief Inspector of Mines of the Union of South Africa, on Nov. 7, aged sixty-two years.

News and Views.

DRS. BOSCH and Bergius, who share the Nobel prize for chemistry in 1931, represent German developments in industrial chemistry which have earned the admiration of the whole scientific and industrial world and have stimulated extensive researches along parallel lines in other countries. Dr. Bosch's name is indissolubly associated with that of Prof. Haber in regard to the catalytic production of ammonia from atmospheric nitrogen, whilst Dr. Bergius's researches on the production of volatile hydrocarbons by hydrogenation of organic material under pressure have already given us the expressive term 'berginisation'. Thus the fame of each rests on the reaction of hydrogenation under pressure leading to materials of international importance. The catalytic synthesis of ammonia originated with Haber and van Oordt's work in 1905, when atmospheric pressure was employed, but as the work progressed, and was taken up by Nernst, Jost, and others, the question of providing adequate experimental facilities for working under pressure arose; the process was adopted by the Badische Anilin und Soda Fabrik in 1910, and Dr. C. Bosch, whose name is particularly associated with studies on the catalyst poisons, took a prominent part in its development. The success with which his pioneering investigations were conducted is illustrated by the world-wide use, at the present time, of the Haber-Bosch process for the fixation of nitrogen.

Dr. F. Bergius, who was born on Nov. 11, 1884, at Goldschmieden, near Breslau, has made the study of the influence of high pressure on chemical reactions his chief interest. This work, which was described in his book, "The Use of High Pressures in Chemical Actions", was preliminary to the development of his widely known process for the manufacture of oil from coal—a process which was first patented in Great Britain so long ago as 1914. The importance of the process to a coal-producing and oil-importing country such as Great Britain is obvious, and it was therefore not surprising that the speakers at the symposium on the British fuel problem, recently held by the British Association, devoted attention to its advantages and limitations.. Much work on the subject has been done under State as well as private auspices, and it is of interest that, on Nov. 24, the production of oil and petrol from coal is to form the subject of an address to the Imperial College Chemical Society by Prof. C. H. Lander, formerly Director of Fuel Research. The award of the Nobel prize for 1931 for physics has been postponed until next year.

The Polish Physical Society, the Polish Chemical Society, and the Society of Polish Electrical Engineers, with the support and assistance of the Polish Academy of Sciences, Cracow, the Polish Academy of Technology, the scientific societies of Warsaw and Lwow, and various other Polish scientific institutions, arranged for a celebration of the Faraday centenary, on Nov. 6, at Warsaw, in the large hall of the Technical High School. The President of the Polish Republic, Prof. Moscicki, and three members of the Government were present; the British Embassy was also represented. After a short introductory speech, made by Prof. St. Pieńkowski, Dr. Ladislas Natanson, professor of natural philosophy in the Jagellonian University, Cracow, delivered a lecture on the "Life and Discoveries of Michael Faraday". Addresses were also delivered by Prof. W. Swietoslawski, of the Warsaw Technical High School, who discussed and explained Faraday's chemical and electrochemical researches, and Mr. T. Czaplicki, who chose for his subject, "Faraday and the Modern Science of Applied Electricity". The proceedings concluded with an exhibition of various pictures connected with Faraday's life and work. The commemorative meeting was an impressive testimony of the deep reverence and gratitude which, in Polish scientific circles, is attached to Faraday's memory.

The following is a list of those recommended by the president and council for election to the council of the Royal Society at the anniversary meeting on Nov. 30: *President,* Sir Frederick Hopkins; *Treasurer,* Sir Henry Lyons; *Secretaries,* Dr. H. H. Dale and Sir Frank Smith; *Foreign Secretary,* Lord Rayleigh, *Other Members of Council,* Dr. J. A. Arkwright, Prof. G. Barger, Prof. W. L. Bragg, Prof. E. P. Cathcart, Mr. A. C. G. Egerton, Mr. R. H. Fowler, Prof. E. S. Goodrich, Prof. G. H. Hardy, Prof. W. N. Haworth, Prof. C. E. Inglis, Prof. O. T. Jones, Sir Thomas Lewis, Dr. N. V. Sidgwick, Prof. A. G. Tansley, Prof. G. I. Taylor, Prof. D'A. W. Thompson.

A recent issue of the *Dalhousie Review* contains an interesting article by Dr. D. F. Fraser-Harris, entitled "Medical Pioneers in Science". In substance, however, this brochure selects and records accurately the upbringing and achievements of those presidents of the Royal Society of London who, successors of Newton, have held medical degrees. This method of discussing the data of biography often affords unexpected comparisons and coincidences. There seem to have been, within the defined period, nine presidents possessing medical degrees, namely: Sir Hans Sloane, Bt. (1727–41), Sir John Pringle, Bt. (1772–78), W. H. Wollaston (June 1820–Nov. 1820), Sir Benjamin Brodie, Bt. (1858–61), Sir Joseph Hooker (1873–78), T. H. Huxley (1883–85), Lord Lister (1895–1900), Sir Charles Sherrington (1920–25), and Sir F. Gowland Hopkins. Of these, only three may be said to have followed medicine or surgery as a means of livelihood, though the remainder were closely associated with medical studies. Sloane was created a baronet by George I., an honour to which no English physician had before attained. Lister was raised to the peerage (1897), the first medical man receiving that dignity. Lately, various character adjectives have been applied to Faraday; the author deems Lister to have been "learned, dignified, gentle, courteous, strong, industrious, modest"—we may surely add that above all he was serene. Eight of the foregoing presidents were married, Wollaston being the exception. He himself was one of the seventeen children of a Norfolk clergyman, whilst Sir Benjamin Brodie was, alike, one of the seventeen children of the rector of Winterslow, Wiltshire.

In connexion with the award of medals by the Royal Society for the present year (Nature, Nov. 14, p. 821), it is interesting to recall that the Copley Medal for 1831 was allotted to Sir George Biddell Airy for his papers on the construction of the achromatic eye-pieces of telescopes and on the achromatism of microscopes, on the spherical aberration of eye-pieces, and for his other papers on optical subjects in the *Cambridge Philosophical Transactions.* Airy was not at the time a fellow of the Royal Society, that honour being given him later, namely, in 1836. In the year previous to this, he had been appointed Astronomer-Royal. Airy was president of the Royal Society from 1871 until 1873, whilst on five occasions he was chosen president of the Royal Astronomical Society. With regard to the awards of Royal medals, it appears that none were made in 1831 or 1832.

In delivering the fifteenth Bedson Lecture at Armstrong College, Newcastle-on-Tyne, on Nov. 13, Prof. John Read dealt with researches on essential oils. He pointed out that the unique flora of Australia belongs to an ancient, slowly-changing order of things which, standing aloof in the isolated Australian environment, has stamped its impress deeply upon the indigenous organic products of the continent. In a laudatory reference to the collaborative work of R. T. Baker and H. G. Smith, the striking fact was mentioned that the merit and value of Smith's work were imperfectly understood in Australia, and "the classical researches of this pioneer chemist of the Southern world remained unappreciated during his lifetime by all but a scanty few of his British colleagues". After giving a general review of the chemical characteristics of the Australian flora, Prof. Read explained some of the recent work which has been carried out in the St. Andrews laboratories upon piperitols and menthols. Among the interesting exhibits was a 50-gram specimen of pure dextro-menthol, prepared by a new process from 200 grams of *dl*-menthol.

IN concluding his lecture, Prof. Read urged his listeners to avoid an undue restriction of vision in their chemical studies. "The conditions under which much of our chemical research work is carried out at the present day", he said, "are such as to produce, in the absence of correctives, a species of mental myopia among chemists. We chemists should strive to acquire balance and a broader vision; to pay more attention to economic and geographical considerations and to the chemical resources of our Empire; to cultivate an interest in botany, agriculture, and other related branches of science: in brief, we should learn to 'think imperially' in chemistry. The test-tube and the still, the transactions and abstracts of our chemical societies, are the tools of our craft; but we are citizens of a wider world. Let us stand back from our laboratory benches occasionally and contemplate the results of our own and our colleagues' researches against the background of our science, our Empire, and our world."

THE Thomas Hawksley lecture to the Institution of Mechanical Engineers was delivered on Nov. 6, by Mr. Ll. B. Atkinson, who chose as his subject the mechanical aspects of electricity. He pointed out that to mechanical engineers some of the modern theories must appear very nebulous. They cannot escape from the fact, however, that electrical and mechanical actions involve an interchange between visible motion and invisible motion. When electrons are moved from positive ions by mechanical motion, there must be some motion somewhere as the equivalent of the mechanical work which will reappear when the surrounding field collapses owing to the return of the electron to the atom to which it belongs. The fact that it has been proved that magnetic fields are due to electron rotations premises rotational energy as the form of the energy hidden from sight, but, nevertheless, existing and recoverable from the magnetic field. These ideas must in some way incorporate themselves into the explanations which will emerge in the future. Physicists, having failed to explain magneto-electrical actions which involve wave effects by the old mechanics, are now trying, with considerable success, to explain the old mechanics by wave effects. But, just as Faraday's and Maxwell's conceptions explained action at considerable distance by action at atomic distance, so explanation of atomic actions by wave mechanics must ultimately resolve itself into finding out the nature of the medium in which the wave takes place. The joy and satisfaction of scientific inquiry lie in the continual striving after fuller explanations.

TEN years ago, practically the only ignition system for the internal combustion engines used on British and Continental cars included the use of a magneto. At the present time, coil (or battery) ignition systems are used on at least eighty per cent of the cars being produced. The chief reasons for the adoption of coil ignition are its lower cost on multi-cylinder engines, the avoidance of difficult problems in the driving of the ignition unit, and the difficulty in finding a suitable type of magneto when high-speed engines are under consideration. Hence the paper read by E. A. Watson on Oct. 30 to the Institution of Electrical Engineers is a timely one. It is now commonly assumed that the amount of energy delivered in the discharge by the ignition system bears no direct relation to the energy necessary for the ignition of the explosive charge. In all cases the latter is a very small quantity and the electrostatic energy stored in the capacitance connected with the sparking plugs is always sufficient to cause ignition of the explosive mixture employed in the cylinder of an internal combustion engine. The mathematical theory of the induction coil, considered as two separate coils, is well known and is directly applicable. Prof. Taylor-Jones has shown how to find the coefficient of coupling which will give the best results. A clear and scientific account is given of the theoretical principles underlying the application of the induction coil to the specific purpose of ignition. The problems still left to the manufacturer are in connexion with small matters of detail, points conducive to cheapness of manufacture and trustworthiness in operation. Coil ignition is now practically a standardised method.

THE Imperial Bureau of Animal Genetics, established under the directorship of Prof. F. A. E. Crew, at the University of Edinburgh, is one of a series of nine imperial agricultural bureaux designed for the purpose of collecting, collating, and disseminating amongst research workers in the British Empire information of a scientific and technical character. It has already made good progress in a work which the dispersal of published contributions to agricultural knowledge in all sorts of odd corners of literature makes increasingly important and even necessary. During 1931 two comprehensive bibliographies have been published. The first contains references to papers dealing with the biology of the fleece, a contribution prepared for the Imperial Wool Conference of 1930, and including works published up to 1929. In addition to the list arranged alphabetically according to authors, there is included a subject index, which forms a useful guide to the varied matter discussed. The second bibliography is more ambitious, and aims at bringing together the chief information upon the subject of fur-bearing animals. This compilation, which has had the advantage of many scientific collaborators, gives a summary classification of fur-bearing animals, and under each species groups the titles of relative papers. It is devised for the assistance of workers interested in the domestication of these useful animals, and includes references to papers on ecology in relation to conservation and utilisation of a natural resource, as well as to papers on the actual breeding of the animals in captivity. The first bibliography (32 pp.) is published by Messrs. Oliver and Boyd at 2*s.* 6*d.* net; the second (36 pp.) is duplicated typescript and may be obtained from the Bureau, price 1*s.*

A SECOND line of co-operative activity adopted by the Imperial Bureau of Animal Genetics is the publication of a *Quarterly Bulletin.* Its purpose, to judge by the three numbers of Vol. 2 which are before us, is to bring its readers in touch with current investigations, partly by the review of books bearing on genetics and relevant problems, and partly by short articles summarising the state of knowledge along different lines. In these numbers the chief summaries deal with lethal factors and live stock breeding, and fur production. The articles are far from exhaustive, but they suggest the scientific outlook, and in the case of fur-production a timely hint is given that the unskilled adventurer may lose much money in attempting to breed for marketable pelts under conditions of locality and climate which make profitable results impossible. It is announced that on the appointment of Mr. Eldon Moore to the editorship of the *Eugenics Review,* his place as Chief Officer of the Bureau has been taken by Dr. F. Fraser Darling.

IN an account of the birds in Mr. Whitley's private zoological garden at Paignton, now being published in the *Avicultural Magazine,* Dr. E. Hopkinson mentions (p. 245) five white specimens of the Australian zebra-finch (*Taeniopygia castanotis*) as having to be kept each in a separate compartment on account of their spitefulness. This is worth noting, as the species, though spirited and well able to look after itself in spite of its very small size, is not normally intolerant, even of its own kind in the breeding-season. It would seem, therefore, as if the white birds, which have only appeared recently, may have a different character from the normally coloured ones. This is certainly the case with a not distantly allied but much larger finch, the Java sparrow (*Munia oryzivora*), in which the white specimens are undoubtedly far more vicious than the normal birds. This may be, however, because the white birds are a domestic race and therefore at home in captivity, while practically all normal specimens are wild-caught and hence more apt to be nervous. In the case of the zebra-finch, however, normal birds are nowadays aviary-bred like the white ones, the species, long known as a free breeder in captivity, having been fully domesticated during this century. If whiteness and pugnacity are often correlated, this may be the reason why the giant fulmar (*Ossifraga gigantea*) is generally white in south polar latitudes and coloured farther north, for it is in polar conditions that the struggle for existence would be most severe among these powerful predatory sea-fowl.

A BREED of Mexican hairless swine has been studied by Elmer Roberts and W. E. Carroll (*Jour. of Heredity,* vol. 22, No. 4), who find that hairlessness is inherited as a simple Mendelian difference in crosses with Chester White. The skin is not entirely devoid of hairs, but they are sparse and the condition is therefore one of hypotrichosis. The heterozygotes have half as much hair as the normal. This condition is quite different from the type of hairless pigs prevalent in some parts of the United States, which is caused by a deficiency of iodine associated probably with goitre in the mother; the young are born dead or die shortly after birth, but the condition can be cured by administration of iodine. Hairless dogs, rats, mice, rabbits, and calves are known, as well as featherless fowls. Some of these factors are lethal. A vigorous naked sheep is, however, described by E. T. Popova-Wassina in the same journal (vol. 22, No. 3). It was born in a flock of black sheep, near Moscow, which had been intensely inbred. The skin was completely bare except for a few hairs on the hind legs and the tip of the tail. The skin was black instead of slate-blue, and the animal—a male—was of full vitality. It is probably a homozygous recessive, brought out by the close inbreeding which had been practised in the flock for twenty years.

WE have received from the British Drug Houses, Ltd., London, N.1, a number of leaflets describing different products issued by the firm. Acriflavine 'B.D.' was the first brand of British acriflavine used as an antiseptic wound dressing: it finds a use in a variety of septic conditions. Caprokol is a brand of hexylresorcinol: it is a urinary antiseptic which can be given by mouth. It is a highly active bactericide, and its action is enhanced by the fact that it reduces the surface tension of the urine so that it has a great penetrating power. It also acts as a soothing anodyne in urinary tract infections. Carotene B.D.H. has the growth-promoting power and anti-infective action of vitamin A, although it is not itself the vitamin. Recent research has suggested that carotene is converted into vitamin A in the animal body. It is issued in the form of pellets. Elixir Valibrom B.D.H. is a pleasant and safe hypnotic: it contains chloralamide, potassium bromide, and extract of valerian. A similar elixir is also issued containing 0·03 per cent morphine in addition. Liver Extract B.D.H. is used in the treatment of pernicious and certain other anæmias, such as that of pregnancy or sprue. It contains the liver fraction which stimulates the production of reticulocytes by the bone marrow. Livogen is a preparation of liver containing vitamins B_1 and B_2, to which has been added hæmoglobin and a yeast extract also containing vitamins B_1 and B_2. It is recommended as a general tonic and for the treatment of secondary anæmias. Manganese butyrate B.D.H. is of value in certain acute local conditions, especially those resulting from staphylococcal infections or in the complications of gonorrhœa. It is administered by intramuscular injection, a one per cent solution being used.

IN December 1930 the Central American Expedition of the University of Pennsylvania explored Yucatan in an aeroplane with the view of locating Maya ruins. A full account of the work of the expedition by Mr. P. C. Madeira appears in the *Museum Journal* (Pennsylvania) for June 1931. Several new sites were found and some were examined, but it is of interest to note that the leader of the expedition believes that the location of sites of ruins by aeroplane, in such a densely forested region as Yucatan, is of little scientific value owing to the difficulty of ground expeditions finding them again. Theoretically it is of course possible to fix the position on the map, but practically the mapped position may be, and probably is, a mile or two in error. This makes it impossible for an expedition cutting its way through the jungle to find the site without great loss of time and the use of many parties. Mr. Madeira suggests that the aeroplane might mark the site by dropping some destructive gas along lines forming a triangle with the site in the middle. Thus an exploring party could pick up the trail of the destroyed vegetation and so find the ruins. Another suggestion he makes is to drop, by parachute, on the ruins "a strongly constructed machine that would send out electrical waves for a considerable period" and so guide explorers to the spot. At any rate, until a sure method is devised of guiding a land party through the jungle to the site of ruins located only from the air, the discovery of further ruined cities by aeroplane seems to Mr. Madeira to be nothing but a fascinating and somewhat expensive sport.

PREVIOUS paragraphs in NATURE have noticed the operations conducted by the organisation known as "River Flow Records" on the rivers Moriston and Garry, in the Ness Basin, Inverness-shire. There has recently been issued a further series of quarterly reports, in two sets, by Capt. W. N. McClean, the director of the organisation, covering the six months from October 1930 to March 1931. These reports contain a detailed record of the rainfall within the basin during the period in question, with comments on the variations at the different gauging stations, and a statement of river-levels with the corresponding flow in cusecs set out in tabular form and the "Remaining Flow-off" from the catchment area in each case. The report on the River Garry also contains an examination of the rainfall records at Glenquoich Lodge on Loch Quoich, for the sixty years from 1870 to 1929, with a series of diagrams showing the annual rainfall, the deviation of the annual rainfall, and the aggregate rainfall to date, given as an excess or deficiency above or below 110 inches per annum. The Meteorological Office reckons the annual average for a period of 35 years (1881–1915) at 110·75 in. The report mentions that a striking characteristic of the record, which is found in those of other Scottish gauging stations, is the comparatively low rainfall of the twelve years, 1878–1889. At Glenquoich the following thirteen years gave a normal average and the twenty-seven years, 1903–1929, a much higher average. The mean of the records of thirty-five Scottish gauges gives similar conditions since 1889, though individual gauges differ very considerably. Copies of the reports can be obtained at the office of River Flow Records, Parliament Mansions, Victoria St., S.W.1.

THE Safety in Mines Research Board Paper No. 69, on the ignition of fire-damp by coal-mining explosives (Part 1, Gallery Experiments. H.M. Stationery Office, 1*s*. 6*d*.), by Grimshaw and Payman, deals with the causes of ignition of firedamp by permitted explosives, and gives suggestions as to the use of such explosives. The experiments show that it is really the conditions under which the explosives are used which determine whether they will ignite firedamp or not, and safety in their use depends as much, if not more, upon the care with which the operation is carried out than upon any specific property of the explosive. The experiments had in view an investigation of the conditions under which a given charge of a permitted explosive will cause ignition of firedamp underground. There is a long discussion of foreign theories of ignition and of the utility of tests. It is considered that the experiments rule out any possibility of utilising flame photography as a means of distinguishing explosives or methods of firing explosives. A shot-hole well placed, well loaded, and well stemmed is regarded as the best preventive of ignition of firedamp by explosives available to-day, and some simple rules which are likely to add to safety in the pit are given at the end of the paper.

THE Report of the Ordnance Survey for the year ending March 31, 1931, shows satisfactory progress in all departments, even if the staff and means available are far from adequate for all the cartographical and other work that is desirable. The Director-General notes the demand for revision of large scale plans of many areas which cannot be met by the Survey. Frequently the work is done by local surveyors employed by the municipality concerned, but the result seldom reaches the standard of accuracy of the Ordnance Survey. As regards small scale maps, a new quarter-inch series of England and Wales has now been published. A new feature of this series is the addition of town traffic diagrams on larger scales, showing the principal roads through the chief towns. They will be bound up with the folded editions, and are ready for sheet 11 of England and Wales and sheet 3 of Scotland. Another feature of interest is the proposal to produce a relief shaded edition of the one-inch map; after experiment, a satisfactory method has been found. The growing number of Ordnance maps printed annually shows that the popularity of these maps is rapidly increasing.

PART 18 of the "Catalogue of Indian Insects", issued by the Government of India, is devoted to the coleopterous family Carabidæ. The author, Mr. H. E. Andrews, has adopted a wide point of view, and the insects listed represent not only the Indian Empire but also the greater part of south-east Asia. The Catalogue is intended as a complete survey comprising all references to the Carabidæ inhabiting this territory. The classification followed is the recent one of T. G. Sloane, with certain adaptations. Thus, one new tribe (Idiomorphini) has been introduced and one tribe (Mormolycini) has been excluded. The arrangement of the Catalogue is alphabetical under genera, and each genus has its species arranged in a similar order, with synonymical and other references, and the areas wherein they are known to occur. Mr. Andrews's contribution, which extends to 389 pages of letterpress, represents the most extensive family so far dealt with in this Catalogue, and is likely to remain a standard for many years to come.

The Executive Council of the National Institute for the Blind has issued its annual report for the year ended March 31, 1931. A full account is given of the work and activities of the Institute with many illustrations. The output of braille books and periodicals was on the whole greater than for many years, and no less than 27,136 bound volumes were produced. The production of manuscript works and textbooks in braille for blind students has been continued by a band of volunteer writers, and this library now numbers 7000 volumes. The income of the Institute has been maintained, but the future naturally gives cause for anxiety, and emphasis is laid on the value of the annual subscription. The British " Wireless for the Blind " fund provided 13,000 wireless sets to date, and it is hoped that a further 7000 sets will soon be distributed, thus equipping with sets the estimated 20,000 blind persons without means of obtaining them.

A new oceanographical journal has appeared from Madrid in *Revista del Consejo Oceanografico Ibero-Americano*. The numbers that have so far appeared contain several important articles in oceanography by authorities in different countries, as well as bibliographical notes and the proceedings of the Council. The same body is responsible for a series of memoirs in oceanography, which includes papers by Dr. J. A. Fleming and J. P. Ault on the last cruise of the *Carnegie*, one by G. S. Huelin on gravimetric work at sea, and a useful list of oceanographical voyages of all countries by Prof. R. de Buen. This list omits few names of any significance.

The seventeenth of the series of lectures on " Physics in Industry ", arranged by the Institute of Physics, will be delivered by Mr. A. Whitaker, on " Physics in Sound Recording ", at the Royal Institution, on Nov. 26, at 5 p.m.

At a meeting of the London Mathematical Society on Nov. 12, the following officers and new members of council were elected: *President*, Prof. A. C. Dixon; *Vice-Presidents*, Prof. S. Chapman, Prof. H. Levy, Mr. T. L. Wren; *Treasurer*, Dr. A. E. Western; *Librarian*, Prof. H. Hilton; *Secretaries*, Prof. G. N. Watson, Mr. F. P. White; *New Members of the Council*, Mr. M. H. A. Newman and Mr. H. T. J. Norton.

It is announced by Science Service that Mr. Masani Nagata has been awarded the Donohoe Comet Medal by the Astronomical Society of the Pacific, for his discovery of the first new comet of 1931. The observation was recorded in Nature for Aug. 1, p. 192.

It is announced in *Science* for Oct. 23 that the John Fritz gold medal, conferred by the four American societies of civil, mining and metallurgical, mechanical, and electrical engineers, has been awarded for 1932 to Dr. Michael I. Pupin, professor of electro-mechanics and director of the Phœnix Research Laboratory at Columbia University, for his achievements as " scientist, engineer, author, inventor of the tuning of oscillating circuits and the loading of telephone circuits by inductance coils ".

The annual Congress of the Royal Institute of Public Health will be held in Belfast on May 10–15, 1932, under the presidency of the Marquess of Londonderry, chancellor of the Queen's University of Belfast. The inaugural meeting will be held on the morning of May 10, and the scientific work of the congress will be conducted in the following sections: Section 1, State Medicine and Municipal Hygiene (including Port Sanitation); Section 2, Industrial Hygiene; Section 3, Women and Children and the Public Health; Section 4, Tuberculosis; Section 5, Pathology, Bacteriology, and Biochemistry.

The latest catalogue of Messrs. Francis Edwards, Ltd., 83 High Street, Marylebone, W.1, is No. 541, giving the titles of upwards of 1300 works dealing with Africa. It should be of interest to geographers and anthropologists.

Messrs. Baillière, Tindall and Cox, 7 and 8 Henrietta Street, W.C.2, have just issued a very useful classified catalogue of current books dealing, respectively, with animal husbandry and agriculture (including horticulture and forestry). The catalogue gives also the titles of certain periodicals relating to the subjects dealt with in the main list.

Applications are invited for the following appointments, on or before the dates mentioned:—A master at the Government Technical School, Kingston, Jamaica, for metal work and engineering subjects—C.A., The Secretary, Board of Education, Whitehall, S.W.1, or The Secretary, Scottish Education Department, Whitehall, S.W.1 (Nov. 23). A research student at the Institute of Pathology and Research, St. Mary's Hospital—The Secretary, Institute of Pathology and Research, St. Mary's Hospital, Paddington, W.2 (Nov. 23). A lecturer in mechanical engineering at the Northampton Polytechnic Institute—The Principal, Northampton Polytechnic Institute, St. John Street, E.C.1 (Nov. 25). A professor of pathology in the University of Sheffield—The Registrar, University, Sheffield (Nov. 27). A junior assistant pathologist at the Royal Sussex County Hospital—The Secretary-Superintendent, Royal Sussex County Hospital, Brighton (Nov. 28). A radium officer for the National Radium Regional Centre at Plymouth (South Devon and East Cornwall Hospital)—The General Superintendent and Secretary, South Devon and East Cornwall Hospital, Plymouth (Nov. 28). A pathologist at the Infants Hospital, Westminster—The Secretary, Infants Hospital, Vincent Square, S.W.1 (Nov. 30). A research fellow in bacteriology at the Lister Institute of Preventive Medicine—The Secretary, Lister Institute, Chelsea Bridge Road, S.W.1 (Dec. 5).

Erratum.—Nature, Nov. 14, p. 821, third paragraph of " News and Views ", last line but one: for " 1300 years " read " 1300 million years ".

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Representation of Crystal Structure.

The atomic structure of crystals is not an altogether simple matter to represent on paper. What is required, of course, is a portrait of a unit cell: that is, of any selected parallelopiped, with atoms at its corners and with just enough volume to include within itself a complete sample of the crystal pattern. A common device is to reproduce in picture form a three-dimensional model of such a cell. Another is to map out the contents of the cell upon one of its six faces. The rays employed for the purpose of projection must be parallel with that edge-direction of the cell which is inclined to the chosen face: thus in some cases the projection is orthogonal, and in others oblique.

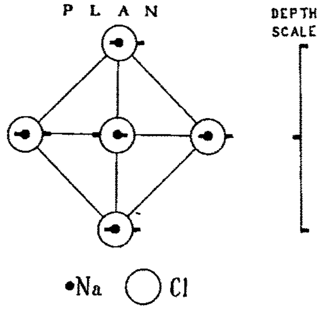

Fig. 1.—Atomic plan of sodium chloride on cube face (001). The symbols bear no relation to atomic volumes. Compare "Introduction to Crystal Analysis", Fig. 32.

Further, it is necessary to adopt a notation to indicate the depth of individual atoms represented on the plan. This depth is always stated as a fraction of the depth of the unit cell as a whole. Two conventions are in common use: (1) the depth of an atom may be shown by varying the depth of shading employed in the ornamentation of its symbol; or (2) it may be expressed by attaching an appropriate number, such as ¼ or 25, where 25 means 25 per cent. Both conventions become difficult at a very early stage of complexity.

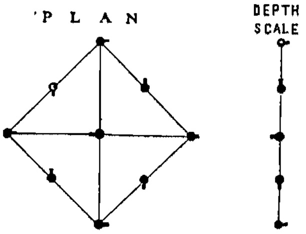

Fig. 2.—Atomic plan of diamond on cube face (001). Compare "Introduction to Crystal Analysis", Fig. 33.

The notation illustrated in Figs. 1-3, while equally simple in principle, admits of wider application. The depth of any atom is indicated in these figures by a pointer, which rotates in clock fashion. If the pointer is directed downwards, the atom lies in the lower half of the unit cell, and vice versa. A depth scale, vertical in the cases illustrated, but oblique where necessary, is added to complete the picture. It is drawn to the same scale as the plan, and its length can be stated in angstrom units.

It is easy with this notation to indicate depths of two or more atoms which happen to be superimposed in plan, even where these atoms belong to different chemical elements. It is also easy to proceed from one plan to another—in fact, to map out the crystal on any desired plane. For example, one can map diamond or calcite at right angles to its cleavage; in which case the origin of the cleavage becomes manifest in alternations of open and close spacing of the atoms.

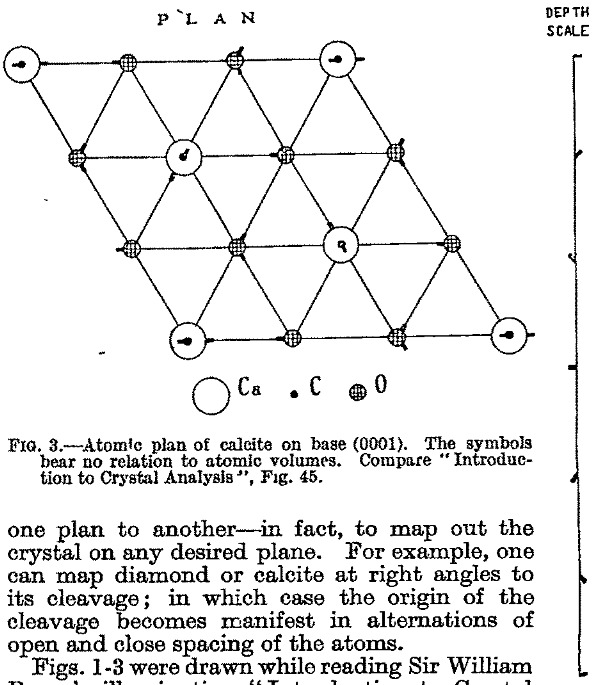

Fig. 3.—Atomic plan of calcite on base (0001). The symbols bear no relation to atomic volumes. Compare "Introduction to Crystal Analysis", Fig. 45.

Figs. 1-3 were drawn while reading Sir William Bragg's illuminating "Introduction to Crystal Analysis", and may be compared with the rather more complex originals, upon which they are based.

Effects of Inadequate Feeding on Insect Metamorphosis.

Mr. Dover in his communication on this subject[1] has confused the phenomenon of metamorphosis with that of moulting. These two phenomena are entirely distinct. It is well known that, whereas all insects periodically moult during their life-cycle, only certain groups undergo metamorphosis. Regarding moulting, his observations support the views to which I subscribed in my papers quoted by him. My conclusions[2] were that the number of moults is in proportion to the length of the larval life, and that moulting cannot be solely, and possibly is not mainly, correlated with growth but is primarily connected with metabolism. Mr. Dover observed that when the larvæ of *Orgyia turbata* completed their life-cycle sooner, they underwent a lesser number of moults than is normally the case. He concluded that the decreased number of moults was due to a lesser accumulation of waste nitrogenous matter. The only difference between our views seems to be that, whereas I connect moulting with general metabolism (which includes excretion), he connects it specifically with excretion, but without advancing evidence in support of his conclusions.

The question of the influence of inadequate feeding on metamorphosis, with regard to which there seems to be a radical difference between Mr. Dover's views and those of many other entomologists, including myself, is of far greater importance. Kellogg and Bell,[3] Northrop,[4] Tangl,[5] Kopec, and others, working on different groups of insects, showed that inadequate feeding, qualitatively or quantitatively, prolonged the larval life of the insect concerned. The observations of Krizenecky[6] and of Szwajsowna[7] on mealworms, however, did not seem to support this conclusion. Thereupon I carried out a series of experiments on mealworms, and found[8] (*a*) that the first essential for the metamorphosis is the full growth of the larva, which under normal conditions is attained a few days before actual pupation, and during these few days the larva does not require any food; and (*b*) that metamorphosis is delayed or accelerated according as the larva is inadequately fed before or after it is full grown.

It is evident that, whether metamorphosis is accelerated or retarded, the metabolic rhythm is disturbed; therefore Mr. Dover's explanation of my observations, namely, "that a comparatively lengthy period of starvation, followed by an equal period of normal feeding, disturbed the metabolic rhythm to the extent of retarding growth", is not very helpful. With regard to his own observations, we note that when larvæ of *Orgyia turbata* were reared on *Crotolaria*, a plant to which they were not accustomed, and which was apparently unpalatable, a heavy mortality occurred among them, and those which survived completed the larval period sooner. From this he concludes that inadequate feeding accelerates metamorphosis. This conclusion is based on the assumption that *Crotolaria* is less nutritious than the usual food plant, which may not be necessarily correct. Before sending this communication for publication, Mr. Dover was good enough to discuss the subject with me. He informed me that he had not ascertained by weighing or otherwise whether the larvæ fed on *Crotolaria* were smaller or bigger than those reared on the usual food plant, nor had he followed the complete history of the individuals fed on *Crotolaria* in order to determine their power of reproduction. Without applying these simple tests, to assume that *Crotolaria* provided inadequate food and to suggest that an insect which has once gained a foothold on the unusual plant may be more numerous than on the favoured ones appears scarcely justified. In this connexion the observations of Parfentev[9] on another species of *Orgyia* are of more value. This author studied the question by a series of carefully controlled experiments, and concluded that inadequate feeding retards metamorphosis and prolongs the larval life, a conclusion which is in consonance with the views of many entomologists, including myself, and is entirely opposed to Mr. Dover's interpretations.

The Spin of the Photon.

RECENTLY a number of papers have appeared on the question as to whether the phenomena of polarisation of light can be explained by the assumption of a 'spin' of the photon.[1] Kastler and Frisch deduce from their experiments that the photon possesses no spin, and Kastler argues further that the phenomena of polarisation should be explained on statistical grounds. Raman and Bhagavantam, on the other hand, argue that the interesting results obtained by Bär and Hanle[2] on the reversal of the state of polarisation of Raman lines when observed in the direction of propagation of the primary beam can be explained only on the assumption that the photons possess spin. They seem to link circular polarisation definitely with a spin of the photon about the line of propagation.

The arguments of Frisch and Kastler are based upon the Sommerfeld-Rubinowicz explanation of the selection principle for the azimuthal quantum number (principle of conservation of angular momentum of atom plus photon), but applying the same principle, and the principle that the atom-magnet can orient itself in any direction making certain definite quantised angles with the external field (as proved by Stern and Gerlach's experiment), it can be shown that the absorption of Zeeman components can never disappear with reversal of the field, but it will be modified on passing through two fields, whether parallel or antiparallel. Hence the experiments of Frisch or Kastler cannot be interpreted in the way supposed by them and show no light on the question of the spin. Secondly, and this is more important, a discussion of the Zeeman effect of the π-components of the D_1 line, assuming that the principle of conservation of angular momentum holds during radiation, shows that there may be photons without any 'spin' whatsoever, although they may show polarisation. It therefore seems unjustifiable to describe polarisation with the aid of a 'spin'. It appears that Bar and Hanle's results should be explained in some other way than that proposed by Raman and Bhagavantam.

A full discussion will appear later.

Light Scattering in Liquids.

As was pointed out by Raman and Krishnan,[1] the nebulosity or wings which appear accompanying the original lines of the mercury arc in the spectrum of the light transversely scattered by liquids consist of nearly completely unpolarised light. These wings arise from an unresolved rotational Raman scattering, their intensity depends on the optical anisotropy of the molecules concerned, and they contribute in a not negligible degree to the total scattering by the liquid. Owing to the fact that it consists mainly of unpolarised light, the existence of rotational scattering affects the observed depolarisation of the total scattered light to a notable extent. This is illustrated by the figures given in Table I., in which measurements with carbon disulphide, benzene, and toluene are shown. The first column of figures gives the depolarisation, as measured with a nicol and a spectroscope with a *very wide slit*, so that the Rayleigh and rotational Raman scattering are superposed.

TABLE I.

Substance.	Total scattering (observed value).	Rayleigh scattering (observed value)	Spin theory (quantum).	Classical theory (Maxwellian)
Carbon disulphide	64·0	56·0	55·5	36·4
Benzene . .	41·5	33·3	33·1	20·6
Toluene . .	45·0	37·0	35·1	22·0

In the second column are given the values obtained using *a very narrow slit*, so that only the Rayleigh scattering is recorded on the plate with the exposures given. The third column gives the theoretical value of the depolarisation calculated on the theory of spinning photons referred to in recent communications by Sir C. V. Raman and S. Bhagavantam. The fourth column gives the values calculated on the basis of the classical or Maxwellian theories of light-scattering. It will be seen that the agreement between the second and third columns of figures is very striking.

Photoelectrons and Negative Ions.

PROF. WELLISH's letter under this title[1] calls for some comment.

In a mixed current of electrons and negative ions traversing a gas, it is usual to assume that the proportion of free electrons will decrease exponentially with the distance covered parallel to the electric force, owing to the combination of electrons with neutral molecules. Thus, the number of photoelectrons surviving in a free state after travelling a distance d will be $N_d = N_0 \epsilon^{-\lambda d}$, where N_0 is the number starting from the electrode. J. J. Thomson[2] has shown that we may put $\lambda = \frac{U}{KX} \cdot \frac{1}{L} \cdot \frac{1}{\beta}$; where X is the field strength; K, L, and U the mobility, mean free path, and velocity of thermal agitation of the electrons; and $1/\beta$ the probability that any one encounter between an electron and a gas molecule will result in their combination. In theory, K and L are both inversely proportional to the gas pressure p, and Townsend[3] finds that K and U are also functions of X: so we may expect that λ will be a somewhat complicated function of X/p^2, even if we assume that β is a constant characteristic of the gas, and not in its turn a function of the electron energy.

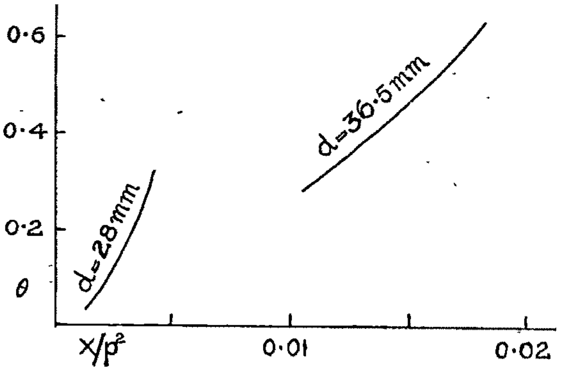

FIG. 1.

Wellish states that, in order to fit the theory to his experimental current/voltage curves, different values of λ are necessary for curves made with different frequencies of the alternating field. This is only to be expected, since the corresponding values of X will be different. The real question is whether a single value of β, not λ, can be found to fit all the curves.

With regard to the experimental procedure, there are serious practical objections to the use of current/voltage curves. The effects under consideration are functions of the field strength, and the actual magnitude of λ will therefore vary along the curves. The exact correlation of theory with experiment is not only very laborious, but also is subject to an unnecessarily wide margin of error. These complications can be avoided by keeping the voltage constant and varying the frequency of the alternating field cycle: the curves obtained in this way are much easier to interpret.

The effect can be studied in detail by my method,[4] in which, by means of two synchronised alternating fields separated by a grid, the current/*frequency* curves are resolved into two clear-cut horizontal 'steps'. From these the proportion of free electrons to total current (Wellish's θ, my N_d/N_0) can be read directly.

A crucial test of Wellish's theory lies in the effect of d, the distance between the electrodes. If no electron captures occur in the body of the gas, as he suggests, then, for given values of X and p, θ should be independent of the distance travelled by the free electrons. I am not at present in a position to make this experiment; but a re-examination of my published data[5] shows that θ can be expressed as a function of X/p^2, for a given value of d, and that when d is changed there is a complete discontinuity in the graph (see Fig. 1). This shows at least that an appreciable fraction of the electron capture must occur in the body of the gas.

Change of Dielectric Polarisation of Carbon Disulphide with Temperature.

ONE of us (J. M.) has determined the changes of density D and dielectric constant E of carbon disulphide with temperature.

On the basis of these data we have computed the dielectric polarisation P, using the formula of Clausius Mossotti:

$$P = \frac{E-1}{E+2} \cdot \frac{1}{D}.$$

The accompanying curve (Fig. 1) represents the results of this computation for the temperature interval from − 60° up to − 112°.

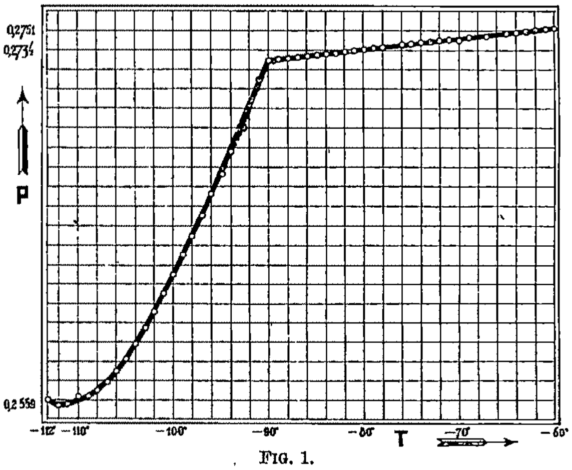

FIG. 1.

The value of P decreases gradually from 0·2751 at − 60° to 0·27372 at − 90° C. At − 90° there appears a sudden drop in the value of polarisation. It should be noted that at this point there appear also a jump in the value of the dielectric constant of carbon disulphide and a distinct change of slope in the density curve. Moreover, this is a point of change from one liquid modification of carbon disulphide into another one, also liquid.

The sudden change of the value of P at $-90°$ suggests that the structure of the carbon disulphide molecule undergoes a change at this point. We have already observed a similar effect with ethyl ether.[1]

Diamagnetism of Liquid Mixtures.

WE have been for the past year working on the diamagnetism of liquid mixtures. Our method was to determine the mass susceptibility by a Curie balance, using a powerful electromagnet of the Pye type. Several mixtures have been studied carefully. By careful adjustments we are confident that our error in susceptibility value is not more than half per cent. In all cases studied, straight lines have been obtained between the mass susceptibility and composition. It is thus clear that the additive law is generally obeyed by liquid mixtures. Our list includes mixtures of benzene with chlorobenzene, hexane, carbon tetrachloride, and nitrobenzene, mixtures of hexane with nitrobenzene, and mixtures of acetone with chloroform.

Density curves obtained in all these cases have shown a departure of nearly three per cent, the maximum being about five to six per cent in the cases of benzene-nitrobenzene and acetone-chloroform. We therefore agree with Ranganadham[1] that the results of Trew and Spencer[2] require correction, but so far we have not been able to obtain departures from the additive law when mass susceptibilities are considered. Work with many other liquid mixtures is in progress.

Duration and Magnitude of a Lightning Discharge.

A SOMEWHAT unusual case of damage by lightning has recently been brought to the attention of the National Physical Laboratory by Capt. A. J. Mayne, Chief Electrical Adviser for the Aldershot Tattoo. An illuminated notice-board was supplied through fuses from a bare overhead line, by means of two cables, of the type used for house wiring, each having a conductor formed of three strands of tinned copper wire each about 0·75 mm. in diameter, insulated with pure and vulcanised india-rubber, a spiral covering of tape, and an outer braid, and suitable for currents up to 8 amperes: the diameter of each cable was about 5 mm. The two cables were taped together at intervals of about ten metres, and were supported by the creosoted wooden terminal pole of the overhead line and one other similar pole.

At a time when the circuit was not energised, a lightning discharge took place through the cable line, and passed to earth down the supporting poles, in each of which a spiral track was cut: the fuses protecting the cable line were shattered, but no damage to the overhead line was evident. As a result of this discharge, the rubber insulation and tape have been cleanly slit throughout their length and the conductor extracted; the outer braiding has been slit and hangs loose; and each copper conductor has been greatly deformed on one side. At certain points the two conductors have partially cohered. There is no evidence of melting of the copper, and, at most points, no burning of the insulation. At a few points, however, and particularly where the two cables were taped together and the conductor remained in contact with the insulation, burning or melting of the rubber and singeing of the braid have occurred.

It is evident that the lightning current was in the same direction in both cables, and gave rise to an attractive force, under the influence of which the conductors cut the insulation as scissors would do, and came violently into contact.

It is of interest to attempt to calculate very roughly the limiting duration and magnitude of the discharge. For this purpose it is necessary to know the temperature rise of the copper, and the force necessary to cut the insulation. The maximum temperature attained evidently lay between 1100° C., the melting point of copper, and 200° C., a temperature at which no damage to the insulation occurs in 1 minute. Some experiments in which a piece of the conductor was heated to a known temperature, placed in contact with the insulation, and allowed to cool naturally, suggest that 700° C. is a probable value for the temperature rise.

An approximate figure for the force necessary to cut the insulation was obtained by laying a piece of the three-strand conductor on a length of insulation resting on a copper plate, and applying pressure with a hydraulic press: the conductor was first run through a bath of solder to avoid spreading of the strands, since the tendency to spread would not be present during the actual lightning discharge. It was found that the insulation and braid were completely cut by a pressure of 150 kgm. per centimetre, the time of application being about 2 seconds, and were not cut by 100 kgm./cm. Taking a spacing of 0·5 cm., the minimum current in each conductor necessary to produce a force sufficient to cut the insulation is 60,000 amperes. This current must have supplied the energy required to raise the conductor temperature by 700° C., approximately 3000 joules per metre, in the duration of the lightning discharge. Hence it may be calculated that the maximum duration of the discharge was 20×10^{-6} seconds.

It may be noted that the average rate of energy input to each metre of conductor was at least 150,000 kilowatts.

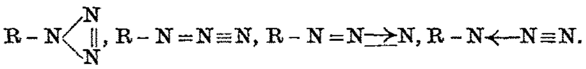
Structure of the Azide Group.

L. E. SUTTON has given[1] measured values of the dipole moments of the *liquids* phenyl azide, *p*-chlorphenyl azide, and *p*-tolyl azide, and applies this evidence to discriminate between the structural formulæ below (1–4). The evidence is strongly in favour of the ring structure (1).



$$\mathrm{R-N}\begin{array}{l}\diagup\mathrm{N}\\ \;\;\|\\ \diagdown\mathrm{N}\end{array},\ \mathrm{R-N=N\equiv N},\ \mathrm{R-N=N}\underline{\longrightarrow}\mathrm{N},\ \mathrm{R-N}\longleftarrow\mathrm{N\equiv N}.$$

1 2 3 4

In contradistinction to this, in each of the *crystalline* azides for which structures have been obtained hitherto, the crystals of sodium, potassium, thallium, and cyanuric azides, (i) the azide group occurs as a short chain, and (ii) it is the central atom of the chain that carries the valence bond of the group.

These differences, in my opinion, are due to an instability inherent in the chain grouping under certain conditions.

(5) 
$${}^{4}\underset{-}{\mathrm{N}} : \overset{\overset{\mathrm{X}}{\downarrow}}{\underset{++}{\mathrm{N}}} : \underset{-}{\mathrm{N}}{}^{4}$$

(6) 
$$\mathrm{X} : \mathrm{N} \begin{matrix} : \mathrm{N}^{2} \\ \cdots \\ {}^{2} : N^{2} \end{matrix}$$

The electronic formula (5) represents a stable group of three nitrogen atoms, provided that one additional electron is supplied from outside so as to make a total of $3 \times 5 + 1 = 16$, for example by means of a polar linkage with an electro-positive radical X.

When, however, a non-polar linkage is formed between X and N, it is no longer possible for electrons to group themselves in octets about the nitrogens of the chain. The stability lost in this way can be regained only by disruption or by the formation of a ring, as, for example, at (6). This is the ring found by L. E. Sutton for the non-polar liquids he examined, and written by him as at (1), in accord with the chemical notation.

On this evidence, the grouping must take the ring form whenever it is bound into a molecule by a non-polar bond, but may take a chain form whenever it is either an electronegative ion or is bound into a molecule by a polar bond.

The dipole moment of (5) consists of (*a*) a moment due to the polar linkage acting along the valency X - N, and (*b*) two moments due to the semi-polar double bonds N - N, which are equal and act in opposite directions. The resulting dipole moment is, therefore, substantially that due to the bond X - N, and so is comparatively small. For (6), also, the dipole moment is small, since the distribution of electrons is balanced for each atom.

The calculated parachor values are nearly equal for the two groupings, being respectively

$$3 \times 12{\cdot}5 + 2 \times 23{\cdot}2 - 3 \times 1{\cdot}6 = 79{\cdot}1$$

and $$3 \times 12{\cdot}5 + 23{\cdot}2 + 16{\cdot}7 = 77{\cdot}4.$$

Slow Combustion of Hydrocarbons.

Two recent papers by S. Lenher[1] on the slow thermal oxidation of ethylene afford very striking confirmation of a modification of Bodenstein's mechanism[2] for the oxidation of acetylene, which I have developed to explain the proportions in which carbon monoxide, carbon dioxide, water, glyoxal, formaldehyde, and formic acid are formed in the reaction. Instead of Bodenstein's reaction

(5) $C_2H_2O_2' + O_2 \rightarrow CO_2 + HCOOH,$

which fails to explain the proportions in which carbon dioxide and formic acid are formed, the deactivating collisions with oxygen are assumed to occur in two ways in a ratio determined principally by steric factors thus:

(5*a*) $C_2H_2O_2' + O_2 \rightarrow CO + CO_2 + H_2O,$

(5*b*) $C_2H_2O_2' + O_2 \rightarrow 2CO + H_2O_2.$

With an additional but very minor reaction

(7) $2C_2H_2O_2' \rightarrow CO + CHO.CO.CH_2OH.$[3]

The scheme, with these modifications, accounts for all the observed phenomena within the limits of experimental error. It is now evident, from very careful analytical work by Lenher,[1] that hydrogen peroxide is produced in the oxidation of ethylene. This can be most readily accounted for by a reaction such as (5*b*) above,

$$C_2H_4O_2' + O_2 \rightarrow CO + H_2O_2 + HCHO,$$

rather than by the less probable deactivation by water suggested by Lenher, and conditions for the formation of dioxymethyl peroxide would be even more favourable. Lenher's kinetic measurements on ethylene, and also those of Thompson and Hinshelwood,[4] show a close parallelism with acetylene and indicate that the reaction proceeds by a similar mechanism. Lenher claims that the large yield of ethylene oxide obtained with short contact time, high temperature, and high ethylene concentration proves the chains to be short and discounts any theory postulating direct formation of carbon monoxide and carbon dioxide from the first collision complex as in (5*a*) and (5*b*). My experiments on acetylene using packed and open vessels,[5] and similar experiments by Lenher[1] on ethylene, show that the chain length in these reactions is at least of the order of 400, and such products as ethylene oxide and methyl alcohol[6] are to be regarded as the result of an alternative non-chain propagating deactivation by the hydrocarbon molecule, which only becomes of importance at high temperatures, high concentrations of hydrocarbon, or special conditions of surface. These views, with my results on acetylene oxidation, will shortly be published in a more extended form.

Occurrence of *Lithothamnion* in the South Indian Cretaceous.

In continuation of my note regarding the occurrence of *Lithothamnion* in certain Cretaceous rocks of the Trichinopoly area,[1] I write to state that I have further been able to recognise similar, or even identical, algæ in a limestone from the Cretaceous of the Pondicherry area. Some sections of this limestone reveal these algæ in such abundance that there is little or no hesitation in calling the rock an algal limestone. The discovery of these algæ in the rocks of the Pondicherry area must be considered as doubly interesting; first because it will now enable us to extend the statement made about the occurrence and importance of these algæ in the Trichinopoly area as being true of the whole South Indian Cretaceous, and secondly as revealing a new field for providing further material for detailed palæontological investigations of the South Indian Cretaceous algæ in general. The stratigraphical position of this algal limestone of the Pondicherry area, and the general facies of its associated fossils, suggest an age corresponding to the lower Ariyalurs (Senonian) of the Trichinopoly area; and hence we may reasonably conclude that, in this Pondicherry limestone, we have an occurrence of *Lithothamnion* even older than that which has been discovered in the Trichinopoly area.

Research Items.

The Cult of the Bull in Scotland.—Mr. A. D. Lacaille, in *Folklore*, vol. 41, No. 3, brings together evidence from place-names, folklore, and archæology bearing upon the existence of a bull-cult in Scotland in prehistoric and protohistoric times. In the west, where Gaelic is still spoken, place-names are coupled with bovines; for example, a wood called 'Coille nan Tairbh' (Wood of the Bulls), near Kilmartin in Argyll. Nearby are several round cairns and other remains and sculptures on a granite outcrop; while a round cairn at Largie nearby yielded one of the most interesting sculptured stones of Scotland on which are figured eight axe-heads, suggesting work of the early bronze age. Names from bulls are given to rivers; for example, the 'Tarff' ('Tarbh', Gael., a bull) or 'Tarbhan', a little bull; 'Loy' from 'Laogh', a calf; for example, 'Alt Fionn Laoigh', 'the Burn of the White Calf'. Not only are antiquities present in the neighbourhood of places designated under an appellation incorporating a bovine name, but also there are legends associated with such features, as well as special practices observed by the people at certain times of the year. One of the most important places of pilgrimage in Scotland was an island on Loch Maree, where ancient rites survived long after the Reformation, associated with St. Mhaolrubh and a sacred well, where a bull was sacrificed on Aug. 25. Reginald of Coldingham records the sacrifice of a bull in honour of St. Cuthbert at Kirkcudbright; and the holy pool of St. Fillan at Strathfillan, Perthshire, effective in curing mental derangement, lost its virtue through the immersion of a mad bull. A legend of the combat between the Red Bull of England and the Black Bull of Scotland is associated with the Pulpit Rock of Ardlui. Representations of the bull are found on sculptured stones of prehistoric and early Christian times, but only in the east and north-east of Scotland.

The Fulani of Northern Nigeria.—Some notes on the Fulani of Northern Nigeria, collected by Mr. G. W. Webster during a residence of twenty-four years, are recorded in *Man* for November. Little can be learned from the settled Fulani, who have intermarried with native tribes and are under the influence of Islam, while the nomad Fulani are shy and inaccessible. A few families admitted the author to their intimate family life. They were startlingly white in appearance and of surprising mentality. They have slim and athletic figures, with beautiful hands and feet, oval faces, and straight or slightly wavy silken hair, usually worn in three to six plaits, but sometimes wound round the head in a single plait and fastened by a silver bodkin with a filigree head, or merely bundled up under a containing cap. Combings or horsehair are used by both sexes to increase the length of the hair. The men have straight or aquiline noses, the women short straight noses or long thin noses, sometimes tip-tilted. The lips are well chiselled, and fine, though often spoilt, according to our ideas, by tattooing of the lower lip, which thickens it and makes it pendulous. The ordinary dress for both sexes is a leather kilt, ornamented with tassels of cowry and shells or beads. It is frequently ornamented with patterns said to be heraldic. The older men wear, in addition, a sleeveless shirt of white cloth, the women a cloth wrap put round the body to form a dress from armpit to calf. The older men wear a phrygian cap or straw hat, as a protection from rain and sun when travelling. Women are usually bare-headed. Boys and girls herding cattle wear the kilt, a tanned skin over the shoulder, and the straw hat. The girls in addition have breastplates of copper, silver, or even calabash. On holidays and festivals, the kilts and jackets are brightly embroidered, and the girls wear necklaces of beads, said to be of great antiquity, with numerous pendants.

The Canada Goose and its Races.—The Canada goose is one of the favourite water-fowl of ornamental ponds in Great Britain, but in its native home it has been a source of annoyance, at any rate to the zoologists. *Branta canadensis* has several geographical races, and in the absence of investigation of the segregation of the races in their far northern breeding grounds, a satisfactory classification of material containing mixed migrants has been impossible. P. A. Tavener, having at hand new collections of breeding and summering specimens from Baffin's Land and elsewhere, has made a fresh attempt to solve the problem (*Ann. Rep.* for 1929, Nat. Mus. Canada, p. 28, 1931). He notes that the experienced sportsman often distinguishes, by habit, stance, action, or voice, races which to the taxonomist appear to be all but identical. As a result of his comparison of characters and sizes the author now groups under the specific name of *Branta canadensis*, three races—the honker or eastern form (*B. c. canadensis*), the western form (*occidentalis*), and the lesser form (*leucopareia*). But, partly on account of its breeding in juxtaposition with *leucopareia* without general hybridisation, he separates *B. minima* as a definite species, in which category he also places *B. hutchinsi*; the latter, apart from niceties of colour, appears to be a diminutive edition of *leucopareia* and *canadensis*.

Larval Freshwater Shrimps from Japan.—Dr. Zu Yokoya, in his paper "On the Metamorphosis of Two Japanese Freshwater Shrimps, *Paratya compressa* and *Leander paucidens*, with Reference to the Development of their Appendages" (*Journal of the College of Agriculture*, Imperial University of Tokyo, volume 11, No. 2; 1931), investigates these two freshwater crustaceans, one belonging to the Atyidæ and the other to the Palæmonidæ. Although describing briefly the various larval stages of each and figuring them, he pays special attention to the development of the appendages and of the muscles attached to them. Both species are found commonly in a pond in the grounds of the University of Tokyo, therefore abundant material was forthcoming, the larvæ also being hatched from the egg in aquaria and partially reared. The larvæ of *Paratya compressa* are rather like those of *Caridina wyckii* as described by von Daday, the larvæ of *Leander paucidens* somewhat resemble those of *Palæmonetes varians* as described by Gurney. *Leander paucidens* has an enormous fifth leg, specially large in the early stages. The author observed a larva in stage IV. catching a larval Ephemera with these precociously developed long legs. It is an interesting fact that these caridean larvæ should feed on insects. In the later stages the change in form of these legs is so great that one wonders whether the food is also changed. The paper is well illustrated by very careful drawings of the larvæ and of all the appendages in each stage, the latter occupying eight double plates. The whole is a valuable contribution to the study of decapod development, especially as little is known of these Japanese larvæ.

Entomogenous Fungi.—Mr. T. Petch has chosen the study of fungi which attack insects as his special branch of mycology. He has spent many years in Ceylon, and is now in England, pursuing his favourite hobby. His most recently published work is entitled "Notes on Entomogenous Fungi" (*Trans. British Mycological Society*, vol. 16, pt. 1, pp. 55-75, 1931). The species described therein are members of the genera *Beauveria, Sporotrichum, Rhinotrichum, Volutella, Hypocrella, Isaria, Nœmosphœrella, Oospora, Tilachlidium, Acremonium, Botrytis, Metarrhyzum, Cephalosporium, Sterigmatocystis, Penicillium,* and *Cordyceps.* Most of the descriptions refer to foreign species, and many of them have not been named before. A study of the genus *Cordyceps* revealed the presence of four species which had an atypical ascus. Instead of the characteristic cylindrical ascus with fusiform spores dividing into part-spores, these species have a clavate ascus with fusiform, non-dividing spores. The name of *Ophiocordyceps* is proposed for this genus.

Chromosomes and Constitution.—A. A. Moffett has a very interesting paper upon this difficult subject in reference to the Pomoideæ in the *Journal of Pomology and Horticultural Science*, vol. 9, June 1931. Earlier work from the John Innes Horticultural Institution has shown, for the cultivated apples, that these strains are polyploid, and that the greater productivity of certain strains can be traced to an even number of sets of chromosomes, whilst triploids are relatively infertile, as similar odd multiple polyploids have proved to be in *Prunus* and *Rubus.* At first sight the basic number of chromosomes in the apple seemed to be 17, with diploids 34 and triploids 51 in the gametes. But the curious secondary association of pairs of bivalents noticed in the pollen mother-cells, occurring after the normal pairing at prophase of nuclear division, has already suggested that these 17 chromosomes represent a complex grouping from an original set of seven, three of which were represented three times and four twice. Moffett has extended these observations through a number of the genera of the Pomoideæ, data being tabulated now for species in ten genera, including that variable North American genus *Cratægus.* Whilst the usual numbers of chromosomes in the gametes seem to be invariably 17 or a multiple of 17, the frequent occurrence of similar secondary pairing of the original bivalent pairs is regarded by Moffett as supporting the view that all the Pomoideæ are secondary polyploids founded on an original basic set of seven chromosomes. It is suggested that the common morphological characters of this group may be associated with this unusual cytological constitution.

Kaolin Minerals.—The results of a long-continued investigation of clay minerals by C. S. Ross and P. F. Kerr are presented in *Prof. Paper* 165 E of the U.S. Geol. Survey, 1931. The older methods of study have been supplemented by applying the X-ray powder-method, and tests of this kind have been effectively carried out on the same materials as those used in the chemical, dehydration, and optical investigations. Complete correlation of results is therefore attained. The conclusion is reached that instead of one kaolin mineral there are at least three distinct species. These are called *kaolinite, nacrite,* and *dickite,* the last being after A. B. Dick, who described the original material from Anglesey. All three have generally the accepted composition $2H_2O.Al_2O_3.2SiO_2$, but some kaolinite varies in the direction of higher SiO_2. Kaolinite is stable over the lowest temperature range; it is formed by the weathering of feldspathic rocks and by thermal carbonate-bearing waters. Dickite is stable at higher temperatures, and seems to have been formed by moderately heated hydrothermal solutions; it is not known as a product of weathering. Nacrite is the high temperature form, and is formed by hypogene processes. These results probably explain most of the current differences of opinion about the mode of formation of 'kaolin'.

Tide-gauge Measurements of Height Differences.—Among other interesting papers and reports included in the *Comptes Rendus* of the fifth meeting of the Baltic Geodetic Commission at Copenhagen, Oct. 13–18, 1930 (pp. 275: Ilmari Bonsdorff, Helsingfors, July 1931), is one by D. la Cour on the determination of differences of height by tide-gauge measurements in Denmark. Great difficulty has been found in levelling by the ordinary optical methods over the broad belts of water that separate the islands of Denmark from the mainland; large systematic errors have been found which render the results uncertain. La Cour has investigated the departures of the water surface in these belts from the horizontal, with the aim of avoiding the need for carrying an optical beam horizontally across the belts; this process of determining differences of height he calls 'quasi-levelling'. He has investigated the water-level by tide-gauges at certain Danish stations, and has found a considerable systematic variation of level, depending on the pressure gradients between Shetland and Aaland, and Calais and Cracow; extrapolating to zero pressure gradient, he finds that the corresponding water-level at Esbjerg is 28 cm. below mean water-level. He shows that changes in the mean water-level over a period of a few years can be deduced with a far smaller probable error when the correction to zero pressure gradient is made than when this is not done. He considers, also, the effect of the rotation of the earth in producing a difference of level across belts along which a current is flowing, and believes that this affords the most accurate means of estimating the difference of level. He finally suggests the experiment of laying a small lead pipe across the strait between Denmark and Sweden, in order to connect the levelling bases of the two countries.

An Effect of X-Rays on Matter.—A number of attempts, generally regarded as unsuccessful, have been made to affect the stability of atomic nuclei by non-radioactive methods. An elaboration of one due to Smits is described by G. I. Pokrowski in the *Physical Review* for Sept. 1. The effect consists in the supposed possession of radioactive properties by bodies when they have been exposed to X-rays. In Prof. Pokrowski's experiments, X-rays from tubes run at about 100 kilovolts were used. Light elements were not affected, but after heavy elements had been irradiated it was found that a new ionisation of gases was detectable in their presence, falling off in intensity with a period of half decay of the order of half an hour in the case cited. Another set of experiments was made which showed that a screen could be observed to scintillate in the same circumstances. By combining the two sets of observations, it was deduced that the energies of the particles correspond with those of weak α-particles, so that the phenomenon, if its reality can be maintained, would appear to be some stimulated form of disintegration of nuclei which are not normally radioactive.

Measurement of High Voltages.—A lecture given by Prof. W. M. Thornton to the Institution of Electrical Engineers and published in the October number of the *Journal*, discusses the possibility of making instruments for measuring very high voltages. This problem is an urgent one at the present time. The conclusion arrived at is that high voltage instruments can be made as simple in construction and as accurate and convenient to use as those for lower voltages. In the absolute form, when an ellipsoid instrument is used, the degree of precision approaches the highest physical accuracy. Using this instrument, Prof. Thornton finds very easily a value for the velocity of light which is in excellent agreement with the best of the standard determinations. Another type of instrument is the corona voltmeter, the action of which depends on the appearance of ionisation at the surface of the corona rod. The lack of an accepted theory of corona formation is a hindrance to the general acceptance of the formula which Prof. Thornton gives, but it is accurate, and he thinks the instrument will soon be developed so as to give very high accuracy. The constancy of hot wire ionisation and spark phenomena in gases leaves little doubt that the effects of ionisation are capable of repetition to a high degree of certainty. The electric wind is not at first sight a promising phenomenon to use for precision measurements, yet Chattock has shown that it is steady within one per cent, and further experiments have confirmed his results. Although not quite independent of the frequency, the ionic wind voltmeter is as accurate as any hot wire bridge can be made. It is necessary to work at voltages below that at which corona appears on the filament. Above this point the instrument may fluctuate several per cent above a mean value.

Optical Rotation and Atomic Dimension.—D. H. Brauns, in the *Bureau of Standards Journal of Research*, vol. 7, No. 3, refers to previous investigations which show that for the halogen acetyl derivates of the monosaccharides glucose, fructose, xylose, and arabinose the differences in specific rotations Cl–F, Br–Cl, and I–Br have the same ratio, 41 : 17 : 21, which is in close agreement with the ratio 41 : 16 : 21 for the distances of the carbon to the halogen atoms in homopolar compounds (mean of values of Arkel and de Boer and of Goldschmidt). The values for the mannose derivatives, however, give the abnormal ratio 41 : 25 : 35. The details for the preparation of the crystalline halogen derivatives of tetra-acetyl mannose, including the iodo-compound, are given in the paper. The behaviour of the mannose derivatives is then studied in relation to space models, and the conclusion is reached that the hydrogen of the first asymmetric carbon, to which the halogen is also attached, is influenced by the atoms of the second carbon acetyl group, whereas such an influence does not exist for the other halogenated monosaccharides. The results show that the study of the principle of optical superposition should be carried out in the light of these configurational peculiarities.

Isotopes of Lithium, Sodium, and Potassium.—The *Journal of the Franklin Institute* for September contains a detailed paper by K. T. Bainbridge on the above subject. Magnetic analysis of the positive rays of lithium from a heated spodumene source showed no change with temperature in the relative abundance of Li^6 and Li^7, in agreement with Aston and Morand. Different results of other observers are considered to be effects of space charge. Ions of the alkali metals were produced from heated natural silicates, the technique being described in considerable detail. Sodium and potassium were examined for the presence of small amounts of isotopes other than Na^{23}, K^{39}, and K^{41}. If Na^{21} or Na^{25} exist at all, they are present to less than 1 in 3000 of the main isotope and Na^{22} cannot be present to an extent greater than 1 in 800 of Na^{23}. From analysis of potassium it is concluded that there is less than 1 part in 1500 of K^{43}, less than 1 in 600 of K^{42}, and less than 1 in 300 of K^{40}, in reference to K^{39}, if they exist at all.

Astronomical Topics.

Comets.—Dr. Bower and Miss Miller found a markedly hyperbolic orbit for Ryves's comet from the August observations, but the October ones show that it does not differ much from a parabola; the following is a close approximation to it:

$$\begin{array}{rl} T & \text{1931 Aug. } 25{\cdot}9447 \text{ U.T.} \\ \left.\begin{array}{r} \omega \\ \Omega \\ i \end{array}\right. & \left.\begin{array}{l} 168^\circ\ 16' \\ 101\ \ 28 \\ 169\ \ 16 \end{array}\right\} 1931{\cdot}0 \\ \log q & 8{\cdot}8704 \end{array}$$

They give the following ephemeris for 0 h. U.T. in *Harvard Card* 184:

	R.A.	N. Decl
Nov. 24	$10^h\ 42^m\ 32^s$	1° 41′
Dec. 4	10 33 4	2 9
14	10 20 13	2 56
24	10 3 57	4 3

The comet is still within reach of moderate instruments, but is fading rapidly. It is important to follow the comet as long as possible in view of the near approach that it recently made to Jupiter; the elements given above indicate that it was nearest to Jupiter on Oct. 10, 1930, the distance being fourteen million miles; it remained within half a unit for more than two months.

Mr. F. E. Seagrave finds the following elements for Nagata's comet from observations made at Yerkes Observatory on July 23, Aug. 5 and 31:–

$$\begin{array}{rl} T & \text{1931 June } 10{\cdot}82188 \text{ U.T.} \\ \left.\begin{array}{r} \omega \\ \Omega \\ i \end{array}\right. & \left.\begin{array}{l} 318^\circ\ 45'\ 39{\cdot}31'' \\ 191\ \ 37\ \ 39{\cdot}20 \\ 42\ \ 27\ \ 28{\cdot}51 \end{array}\right\} 1931{\cdot}0 \\ \log e & 9{\cdot}9707006 \\ \log q & 0{\cdot}0137314 \\ \text{Period} & 62{\cdot}9261 \text{ years} \end{array}$$

The period is probably too short, but there is little doubt that the orbit is an ellipse of moderate period.

Mr. Durrad's announcement of a comet in the northern sky, Nov. 5–Nov. 9, proves to have been erroneous; the comet does not exist.

Mutual Eclipses of Jupiter's Satellites.—Before the time when these eclipses were predicted they were very seldom observed. The Rev. T. W. Webb in his well-known "Celestial Objects" (1881 edition) stated that there was only one recorded instance. The duration of the eclipses is brief and they are likely to be missed unless the observer is forewarned. The Computing Section of the British Astronomical Association undertook some years ago to predict these phenomena, and also those in Saturn's system; these predictions have led to many of these phenomena being observed; the results should be of value in improving the elements of the orbit planes; eclipses by Jupiter are of little use for this purpose. The seasons for such eclipses recur every six years, when the orbit-planes of the satellites pass through the sun; one of these seasons has just begun, and Major A. E. Levin, who is both president of the Association and Director of the Computing Section, devoted part of his presidential address on Oct. 28 to this subject. The geometry of the eclipses is somewhat intricate, but that of the mutual occultations, as seen from the earth, is still more so. The predictions are published in the British Astronomical Association Handbooks for 1931 and 1932. The next one that is visible in England at a convenient hour is the eclipse of II by I early on Nov. 23; it begins at $1^h\ 20^m$ A.M. and lasts 6 minutes. There are many visible ones in December, as Jupiter then rises earlier.

Educational Broadcasting.

AMONG the many discussions at the British Association centenary meetings which received comparatively little publicity was that which followed Prof. Winifred Cullis's paper on "Broadcasting in Adult Education". There are few more hopeful signs amid our present difficulties than the attempts which are being made to utilise for instructive purposes the new powers and forces which science has placed at our disposal in broadcasting and the cinema. It is generally admitted that progress in the exact or physical sciences, such as chemistry, physics, engineering, has far outstripped progress in the social sciences. Partly, no doubt, this is due to the disparity between the volume of research in these fields as compared with research in the physical sciences, but the prejudices and conservatism which are still widely prevalent in such fields as eugenics, education, and psychology are a contributing factor which is largely responsible for the absence of a true social science or sociology.

Progress in this field depends not only on research in biology and anthropology but also to a very large extent on the education of the community, if the results of scientific research are to find application. Prof. Cullis described the admirable experimental work which has been initiated in adult education since the establishment of the Central Council for Broadcast Adult Education in 1928. The series of pamphlets on "The Changing World", recently issued by the British Broadcasting Corporation as an introduction to a series of evening talks to be broadcast on Mondays to Fridays from Sept. 28, 1931, to March 25, 1932, illustrates the considerable progress which has already been made with the two main problems presented by the development of a specialised programme technique and of interesting the listening public.

These attractive pamphlets demonstrate the possibility of securing simple, informal, and continuous treatment of live subjects which are of wide general interest and related to experience in a way which appeals to a general audience. They are designed not only to arouse interest in the future talks but also to encourage the formation of study or discussion groups, and contain lists of books dealing with the various topics, which assist further reading and the attainment of a balanced and impartial view.

As its title indicates, the present series of pamphlets has as its main purpose the practical object of assisting the listening public to understand more fully the changes which are taking place in industry, art, and politics largely through the impact of science. This is fundamental work if the community is to have any real capacity to sort out the issues and to lend its continuous and intelligent support to policies which will enable civilisation to regain control over events.

The pamphlet by Prof. Henry Clay is introductory to twenty-four talks on industry and trade, and gives an outline of the ways in which changing wants have shifted prosperity from the basic industries or those supplying the necessaries of life to those that supply luxuries. Prof. Clay suggests that British industry is possibly losing trade because it persists in supplying goods that will last, when its customers chiefly desire variety and novelty. Into this picture, changing conditions in regard to population and emigration are fitted as a background to the factors of technical progress and mass production, upon which discussion is sometimes exclusively centred. Tendencies in industrial organisation and their economic effects, both in relation to the persistence of poverty and the relations of government and industry, are reviewed in an impartial way that opens up wide and fundamental questions.

It is all to the good that such questions as the relations between technical advance and the maldistribution of economic prosperity should be examined widely in this way. Too often the discussion is limited by prejudice or is characterised by an absence of perspective, and Prof. Levy's essay on science in perspective endeavours to place science in its rightful position in regard to the changing conditions under which we live. The rate at which scientific and technical development has proceeded in the last century is probably a prime reason why even yet the gap between scientific or technical advance and social, political, and economic developments is scarcely realised, still less the danger which confronts premature attempts at legislation with inadequate knowledge. Here, as well as in the demonstration that science has provided us with a fresh medium in which art can find expression and, above all, with the means and technique to plan our future, the series of talks which Prof. Levy introduces should greatly promote the interpretation of the true relations of science to society and culture.

Fundamental questions are also raised by the talks on the modern State to which J. A. Hobson writes an introduction. These, too, envisage the part which the specialist is called upon to play in the evolution of order and reasoned control in the sphere of politics if the modern State is to be adequate for the increasing demands made upon it. Existing parliamentary institutions are admittedly ill-adapted to deal with many of the problems, such as those of the relations between capital and labour, town industries and agriculture, manufacturing and distributive trades, key industries, transport, atmospheric pollution, etc., now confronting the State, and departmental action is frequently either ill-informed or unguided by a considered policy. The development of new methods cannot come without the help of scientific workers, and their help cannot be effective unless public opinion understands and appreciates the contribution they have to offer. So, too, in the international sphere, even yet society is slow to realise how imperative science has made the need for co-operation, and that both our material and international life needs replanning as an organic whole in which the co-operative effort of all classes of society and of all nations make their particular contribution to the common weal.

This is no Utopian ideal: it is a practical proposition. As Mr. John MacMurray points out in an introductory essay to the talks on education and leisure, the maintenance of an advanced civilisation depends upon the preparation of the minds which live in it and by it so that they can meet the demand for constant adaption to new conditions, for elasticity and versatility of mind. Primarily this is an educational problem, and the method of education by broadcasting offers a prospect of countering the inertia and mechanisation of mind for which our educational methods far more than our industrial conditions are responsible. If we can acquire the capacity to change our opinions continuously, in a balanced and controlled fashion, by a continuous testing of them against the changing facts of experience—which is only another name for a scientific outlook—we shall find that modern industrial conditions, and the wider services rendered by the modern State, so far from repressing or cramping individuality and personality, offer it wider opportunities. To learn the use of leisure is to learn how to live and to discover the way to control and transform the forces which, unchecked, threaten the existence of our civilisation.

Control of West Indian Insect Pests.

THE reduction of insect damage in all parts of the British Empire is a problem of primary importance. Adequate and reliable physico-chemical methods are available, yet in many parts of the world their cost, or the conditions governing their application, render them essentially unsuitable. Some other avenue of approach has to be opened up in these circumstances, and a method which shows evident promise is the practical utilisation of the parasitic and predaceous enemies of pests, or, in other words, biological control. In 1928, Dr. J. G. Myers, of the Imperial Institute of Entomology, was commissioned to devote two years' study to the possibilities afforded by biological methods of control in respect to the main insect pests of agriculture in the British colonies of tropical America. A preliminary report by Dr. Myers on his investigations has recently been published by the Empire Marketing Board.* In this report he discusses the main geographical, topographical, meteorological, biological, and agricultural conditions upon which the distribution and prevalence of insect pests presumably depend. At the same time there is reason to believe that such factors have a very direct bearing upon the prospects of applying biological control methods.

In carrying out his exploratory mission, Dr. Myers has visited most of the West Indian Islands and also parts of the mainland of South America. Notwithstanding the extensive area covered in these travels, he has been successful in assembling a large amount of practical information. Since sugar-cane is the most important crop in the British West Indies, the pests affecting it, naturally, received the most attention. The most important of these latter, in the region as a whole, is the small moth-borer (*Diatrœa* sp.). While this insect has numerous parasites, only two appear to be reasonably efficient. The most valuable of these seems to be *Lixophaga*, which has accordingly been introduced into Barbados and Antigua. As regards the notorious cane-froghopper of Trinidad, which still remains a pest of the first rank, no effective parasite has yet been discovered, though the possibility of its being found in the mainland remains for the future. The large moth-borer of cane (*Castnia licoides*) is now serious only in Trinidad; it is controlled by flooding the fields in British Guiana. Since it is increasing in Trinidad, an effective parasite is greatly needed. While no parasites are as yet known, the discovery of the original plant-host of this insect by Mrs. Myers is held to render the search more likely to prove successful. The cane root-borer (*Diaprepes abbreviatus*) is likewise a very serious pest in Barbados. The discovery of an effective egg-parasite of two allied species in Haiti and Montserrat has rendered the problem more hopeful, and its introduction into Barbados is being arranged for.

In addition to sugar-cane, the insect pests and their parasites of cacao, cotton, mahogany, banana, coffee, and so on, also come under consideration. In these connexions it needs to be pointed out that, for several of the pests, little hope is expressed that suitable parasitic enemies will be found within the confines of the West Indies or the adjacent mainland. Certain of the injurious species of insects are Old World pests which have become accidentally introduced, without their natural parasites or predators, into the West Indies. There are other cases in which the same pest, or closely allied species, is much more effectively parasitised in Africa or the Orient than in tropical America. Taking facts of this kind into account, the possibility of introducing suitable parasites into the West Indies from the Old World tropics is one which requires fullest consideration, since it may lead the way to the permanent control of the pests concerned. With the cacao thrips, for example, Dr. Myers suggests that a species of parasite from the Gold Coast may prove to be a useful introduction. Against cotton-stainers (*Dysdercus*) certain tachinid flies from Queensland or Nigeria are suggested, and for the banana-borer (*Cosmopolites sordidus*) it is recommended that a search for possible parasites should be made in New Guinea.

If the suggestions made in this report be translated into practice, they will lead to experiments of the utmost value in testing the soundness of the biological principles and ideas that are involved. Difficulties are likely to be encountered in the transit of living material of this kind over vast tracts of land and water. With the increase of aerial communications such troubles will become greatly reduced. The aeroplane, it may be added, has already been adopted by Dr. Myers in the transmission of moth-borer parasites from Cuba to Antigua, whence they were sent on in cold storage to Barbados.

This report should be read by all interested in the subject, and due credit must be given to the Empire Marketing Board, through the financial provision of which the investigations recorded therein were rendered possible.

* Empire Marketing Board. A Preliminary Report on an Investigation into the Biological Control of West Indian Insect Pests. By Dr. J. G. Myers. (E M B 42.) Pp. 173. (London. H.M. Stationery Office, 1931.) 1*s*. net.

Measurement of Pressure and Temperature in the Upper Atmosphere.

DR. A. K. DAS, B. B. Ray, and D. N. Dasgupta, of Alipore Observatory, Calcutta, have sent a description of apparatus designed to yield measurements of atmospheric pressure and temperature at various heights. The advantages claimed over the ordinary meteorograph are that the required information is available within a very short time and at small expense.

For determining pressure, a small glass bulb drawn out at one end into a narrow spiral tube is used. A small pellet of strong sulphuric acid is introduced into the tube; the apparatus is then placed in a chamber with glass windows, the air of which can be gradually removed by a pump. The pressure is shown by a suitable manometer. Exhaustion is carried to the point when the pellet of acid is just reaching the open end of the tube, and the pressure at this moment is observed. The apparatus is then placed inside a light box packed with non-conducting material, the open end of the tube projecting beneath the box so as to overhang a small bowl containing a mixture of sugar and potassium chlorate. It is attached at some distance below a balloon, which carries it up until the pressure has fallen to that value which will allow the acid to emerge and explode the mixture in the bowl, the smoke of the explosion being observed from the ground in a theodolite. Measurement of the angle subtended by the line joining the balloon and the apparatus, and of the angular elevation of the latter, enables the height at which the explosion occurs to be measured.

A slight modification of the arrangement, illustrated by Fig. 1, allows temperature to be measured instead of pressure. As before, we start with air at surface temperature and pressure enclosed by the pellet of acid, but the explosive mixture is enclosed in a sealed copper vessel (*E*). The bulb is packed in non-conducting material, so that it is only the temperature of the explosion chamber that changes when the apparatus is carried up beneath a balloon. The fall of pressure due to the fall of temperature allows the pellet of acid to emerge from the spiral tube at a temperature that is determined by a special experiment on the same lines as that made for calibration of the apparatus for pressure measurement, the temperature in this case being varied.

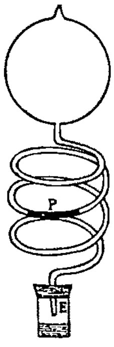

FIG. 1.

It will be seen that for every individual reading of pressure and temperature a special calibrating operation must be made in addition to the construction of a new apparatus. These drawbacks do not necessarily imply that the method is unworkable. A more serious objection is that the method of determining the height of the explosion is obviously liable to serious error unless the altitude is small compared with the highest altitudes attained by the balloon meteorograph for which this apparatus is proposed as a substitute. Its possibilities could be estimated if practically simultaneous sets of values of pressure and temperature were obtained, for the values of pressure could be calculated by Laplace's equation from the observed values of height and temperature, and could be compared with those found experimentally. The apparatus when used for measuring temperature must necessarily ignore inversions of the ordinary fall of temperature with height, and so could never give the thermal structure of the atmosphere in great detail.

Since the above communications were received, Dr. A. K. Das has forwarded a description of a modified form or extension of the device which he has specially designed to supply the missing information. It is shown in Fig. 2.

Glass is used throughout, except for the cork *c*. The vessel *V* contains a small quantity of potassium chlorate and sugar. The shaded parts contain strong sulphuric acid, the unshaded parts air. There is a constriction in the upper horizontal length of tube and a valve *v*, consisting of a glass tube drawn out at each end, which allows acid to travel from left to right only. The whole is packed in cotton-wool, except for the bulb *B* and a part of its stem, and is carried up by an ordinary pilot balloon. So long as temperature is decreasing, the valve is closed and acid is sucked up the stem of *B* owing to the fall of temperature and pressure in *B* through the capillary tube the open end of which is labelled t_1; but as soon as an inversion of temperature is encountered and the pressure in *B* is increased, the valve opens and a drop of acid emerges at t_2 so as to explode the mixture below it. The smoke of the explosion is observed through a theodolite, and its height, which is that of the inversion, is measured by the 'tail-method' described above. The partial filling of the apparatus with acid appears to offer no difficulty, the acid being sucked in through t_1; subsequently some acid is withdrawn from t_1.

Dr. Das does not say whether the apparatus has been tested. A difficulty that at once suggests itself is that of ensuring that the charge shall not be exploded prematurely by a rise of temperature at ground level. Sensitive thermograms show that the air near the ground is constantly varying in temperature whenever a wind is blowing, the effect being due largely to turbulence of the air. It would appear that the bulb *B* would need to be insensitive to these if a premature explosion is to be avoided; at the same time, the balloon that carries the apparatus up must rise quickly if the former is to remain visible to high elevations, and, if the bulb is not very sensitive, inversions may fail to be recorded unless they extend through a considerable height. Ingenious though the device may be, it seems very doubtful whether it or those formerly described will prove to be practical substitutes for apparatus of the type already in use with registering balloons.

E. V. NEWNHAM.

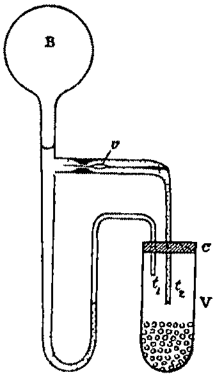

FIG. 2.

Prehistoric Society of East Anglia.

IN his presidential address before the Prehistoric Society of East Anglia on Oct. 7, Mr. J. P. T. Burchell took as his subject the relation of Neanthropic man to the ice age. Mr. Burchell pointed out that a convenient datum line in the quest for the correct geological horizons of the successive cultural stages is provided by the deposits of the 100 ft. terrace of the Thames, and the fact that north of the Thames the Acheulean and Mousterian cultures overlay the lower Boulder Clay. Recent work on the upper glacial deposits of the Yorkshire coast and the estuary of the Humber was correlated by Mr. Burchell with the discoveries made in the Brown Boulder Clay of Hunstanton by J. Reid Moir, and advanced in evidence of a late Pleistocene, Aurignacian-Upper Mousterian stage having been succeeded by climatic conditions which resulted in the formation of the Brown Boulder Clay of the Hunstanton and Lincolnshire coast and of the Coombe deposits (? Boulder Clay) of Yorkshire. Examination of the Lower Estuarine Clay of Northern Ireland had revealed a palæolithic industry of Magdalenian character which must predate the formation of that deposit.

At the same meeting, Mr. A. L. Armstrong described an open-air site at Scunthorpe, Lincolnshire, where an Azilian-Tardenoisian floor, covered by blown sand, was found to be superimposed upon a late Aurignacian deposit. This confirms the sequence already observed in the cave-floor deposits of Mother Grundy's Parlour, Cresswell Crags, Derbyshire, where excavations carried out by Mr. Armstrong in 1924 revealed the gradual development of Upper Aurignacian culture in England and established the fact that this development was of a distinctive character and practically free from Magdalenian influences, while it was found to be overlain by an Azilian-Tardenois culture—the microburin appearing in the last few inches.

Excavations in the Mendip caves and elsewhere have since confirmed these conclusions and it is now recognised that the latest phase of this developed Aurignacian culture is essentially an English one.

Hitherto, definite occupation sites have been confined to caves, but four years ago what appeared to be an open station was located on the North Lincolnshire Cliff Range, in the Scunthorpe district. This has since been consistently examined each year and the original conclusion proves to be correct. The site, though confined to a limited area, has yielded a typical series of developed Aurignacian tools, including long batter-backed blades, keeled scrapers, and burins of various types; also microlithic blades.

The Scunthorpe area has long been known as one of the type stations of the Azilio-Tardenoisian culture in England, and the Upper Aurignacian site forming the subject of this communication is situated within a few miles of one of the areas where pygmy tools are most abundant. The industry represented, however, is free from Tardenoisian influences. Pygmy tools are extremely scarce, and it is believed to be a representative site of the native culture upon which the Azilian and the Tardenoisian was engrafted. Tools which appear to belong to the same cultural epoch have been collected on the ridges southwards towards Lincoln, occurring upon the surface together with tools of later industries, and what is likely to prove a second definite occupation area has now been located in the vicinity of Willoughton and is under examination.

The Rubber Research Institute of Malaya.

THE annual report of the Rubber Research Institute of Malaya for 1930, covering the fourth year of active operations, shows that in spite of difficulties caused by shortage of staff, very considerable progress has been made. The Soils Division has continued its work on the manuring both of immature and mature rubber, and although the low price of rubber has induced caution in the application of artificial fertilisers, it has been possible to obtain valuable data regarding the effect of nitrogen, and nitrogen and potash together. A paper is to be published shortly, summarising our information on manuring the rubber tree, and the Soils Division is also co-operating with Imperial Chemical Industries, Ltd., and Malayan Fertilisers, Ltd., in similar experiments.

Other work has been concerned with practical methods of soil conservation and particularly the value of cover crops, and there is increasing realisation that the mere growth of a cover is not a universal remedy for trees in poor vegetative growth. Small fertiliser dressings, given individually to the young trees, seem a more economic way of inducing rapid growth without prejudice to future soil fertility.

In spite of the absence of a head of division, the Botanical Division has made considerable progress with its investigations on the improvement of *Hevea* planting material by vegetative means and on the response of the tree to different methods of tapping. This work, carried on not only at the experimental station but also in co-operation with various estates throughout Malaya, is providing information on the replanting of old areas which are becoming wasting assets through root disease in the old trees, as well as assisting the selection of new clones from high yielding trees or seedlings of known origin. Tapping experiments have indicated the existence of three or four very promising new Malayan clones.

The Chemical Division has continued its work on the separation and characterisation of latex constituents, particularly on the non-caoutchouc constituents which affect so largely the properties of raw and unvulcanised rubber. In addition, investigations have been carried out on the efficiency of sheet manufacture, the drying of crepe and sheet, the cause and elimination of defects in lower grade rubber, and the preservation and concentration of latex. Methods of spectrographic analysis are being developed by the Institute for soil investigations and for such problems as the effect of minute traces of certain metals on the properties of raw rubber.

University and Educational Intelligence.

CAMBRIDGE.—R. J. Pumphrey, of Trinity Hall, has been appointed University demonstrator in the Department of Zoology.

A grant of £125 has been made from the Balfour Fund to L. C. Beadle, of Pembroke College, for research on the biology of African lakes.

The managers of the Pinsent-Darwin studentship in mental pathology give notice that an election will be made in December. The studentship is of the annual value of not less than £200, and is tenable for three years. The student must engage in original research into any problem having a bearing on mental defects, diseases, or disorders; but may carry on educational work concurrently. Applications should be made before Dec. 5 to the Secretary, Pinsent-Darwin Studentship, Psychological Laboratory, Cambridge.

EDINBURGH.—The following appointments of lecturers have recently been made:—Mr. E. G. Dymond, in natural philosophy; Dr. E. L. Ince, in mathematics; Dr. R. A. R. Gresson, in zoology (cytology); Dr. Peter Gray, in zoology (vertebrate embryology); Lieut.-Col. S. Hunter Cowan, in forest engineering.

AMONG the honours approved by the King, arising out of the recent dissolution of parliament, is that conferred upon Sir W. Martin Conway, who has been made a baron. Sir Martin Conway was member of parliament for the Combined English Universities from 1918 until 1931.

THE Carnegie Foundation for the Advancement of Teaching has issued its twenty-fifth annual report, for the year ending June 30, 1930. Dr. Henry S. Pritchett, who was associated with Andrew Carnegie in organising the Foundation in 1905, presided over its administration from then until August 1930, when he made over charge to Dr. Henry Suzzallo. Starting with an endowment of ten million dollars, the Foundation has grown until its resources now amount to more than thirty-two million, whilst its annual expenditure, chiefly on pensions for University officers and teachers and their widows, is not far short of two millions. Among the topics of outstanding interest dealt with in the president's report is that of American college athletics. Dr. Pritchett exposes the too common exploitation of the student, his diversion from genuine college study and social life, his service under professional trainers in preparation for a commercial show before the public. As an indication of the importance of the rôle football plays in American university finances, he cites the fact that at Harvard the income from athletics (almost wholly from football) is one and a quarter million dollars, as compared with an income of three millions from tuition. In connexion with the study of the relations of secondary and higher education, which is being conducted by the Foundation jointly with the Pennsylvania State Department of Public Instruction, two comprehensive examinations have been administered in some fifty colleges and universities with the special object of measuring effective knowledge as distinguished from raw information. The results indicate that the American system of term courses with term examinations and credits fails lamentably as regards what is supposed to be the central purpose of the college, namely, teaching the student to think. Incidentally, they indicate better mental capacity in students of the sciences than in students of arts subjects.

Birthdays and Research Centres.

Nov. 22, 1875.—Prof. L. N. G. Filon, F.R.S., Goldsmid professor of applied mathematics and mechanics in the University of London and Director of the University Observatory.

Recent investigations have confirmed that double-refraction produced artificially by stress in transparent materials shows local anomalies of dispersion similar to those caused in ordinary refraction by the usual absorption bands. The present anomalies, however, do not seem to be connected with any absorption bands in the material, and their cause and the mechanism of their appearance is still a mystery. The first step towards the solution must be the collection of accurate data for a number of materials, particularly glasses or jellies of graded composition. For this purpose the collaboration of one or more manufacturing firms is essential; workers to carry out the observations, which are delicate and laborious, are also badly wanted.

The effect in question seems likely to throw a good deal of light upon the interaction of radiation and matter in the solid state, and, so far, has been studied only in a preliminary manner.

Nov. 23, 1864.—Sir Peter Chalmers Mitchell, C.B.E., F.R.S., secretary of the Zoological Society of London.

I fear that the increasing burden of administration will leave me no time even to work out certain anatomical investigations which I had to drop during the War. Indirectly I am continuing to study in London and at Whipsnade the relations of animals to light, heat, and fresh air.

A particular inquiry that ought to be taken up is the comparative study of the voices and sounds made by mammals, reptiles, and amphibians. I have no doubt that information interesting in itself and throwing light on systematic affinities could be got. As an example: kangaroos are habitually silent animals, but a kangaroo which is frightened or excited when it is being anæsthetised has a voice very like that of the marsupial wolf.

Nov. 26, 1889.—Prof. H. R. Robinson, F.R.S., professor of physics in the East London College, University of London.

With some of my colleagues at East London College, I am engaged in refining the methods of ‘ magnetic spectroscopy ’ for secondary cathode particles. We hope to elucidate some of the finer details of the interaction of X-rays and bound electrons, and we intend to increase the absolute accuracy of the measurements. Increased accuracy will enhance the utility of these methods in supplementing the data of X-ray spectroscopy, and will also remove some of our uncertainty as to how far discrepancies in the existing measurements may be ascribed to inconsistencies in the accepted values of the fundamental atomic constants.

Nov. 27, 1888.—Dr. Ezer Griffiths, F.R.S., principal assistant, Physics Department, National Physical Laboratory.

My work falls within the domain of physics applied to industry. The problems are largely determined by the wishes of various committees. A few of the investigations are: heat transmission to banks of piping such as are used for air cooling; hygrometry at temperatures below and above normal temperatures; the study of the thermophysical properties of refrigerants; determinations of the thermal resistivity of the soil throughout the year by a method utilising an electrically heated sphere buried in the ground; methods of measuring the amount of water in fogs; the measurement of the heat of formation of nitrous oxide.

Occasionally an investigation takes one far afield. The study of the variables causing loss of ‘ bloom ’ on frozen lamb necessitated a detailed study of the entire chain of processes from the killing floor in New Zealand to the London market.

Societies and Academies.

London.

Royal Society, Nov. 12.—**A. Fowler and J. S. Badami**: Spectrum of the hydrogen–nitrous oxide flame. Observations of the bright cap or cone which appears near the base of the hydrogen–nitrous oxide flame in a mixed jet have shown that the spectrum is closely similar to that of the ammonia–oxygen flame. It differs from the latter in the greater intensity of the HO and NO bands and the lower intensity of the NH_2 ? bands, the NH band at λ3360 being about the same in both.—**S. H. Bastow and F. P. Bowden**: On the contact of smooth surfaces. The experimental work has shown that it is very difficult to place surfaces together without dust or solid particles coming between them. When elaborate precautions were taken to eliminate dust and the surfaces were scrupulously clean there was no evidence for ‘ floating ’. A polished glass plate lowered on to a similar plate in air at atmospheric pressure sank down quickly to within a fraction of a micron of it. This small separation, which represents the limit of smoothness of the plates, was the same whether they were in high vacua, air, alcohol vapour, liquid alcohol, or water. The apparent ‘ floating ’ at a height of 4 microns is due to dust or solid particles between the plates.—**W. B. Mann and B. G. Dickens**: The thermal conductivities of saturated hydrocarbons in the gaseous state. Experiments have been carried out with methane, ethane, propane, and normal butane using the hot-wire method of investigation. The results obtained for the saturated hydrocarbons indicate a decrease of conductivity with each addition of a CH_2 group. Moreover, on plotting the thermal conductivity of the gas at 0° C. against the molecular weight ($O_2 = 32$) it was found that a smooth curve could be drawn through the four points obtained. This curve was found to be hyperbolic. A definite variation of the temperature coefficient with molecular weight is also indicated by the experimental results.

Edinburgh.

Royal Society, Nov. 2.—**G. W. Tyrrell and Martin A. Peacock**: The petrology of Iceland (2). The petrography of the acidic and intermediate intrusives and extrusives. The acidic and intermediate igneous intrusive rocks of Iceland were found to occur as relatively small stocks, and bosses, sills, dikes, and veins, together with extrusive domes and lava flows. They cover only one per cent of the total area of Iceland, and are thus very much inferior in bulk to the dominating basaltic lavas.—**Tudor Jones**: The primitive conducting mechanisms of the vertebrate heart. An introduction to the study of their appearance and development in *Lepidosiren paradoxa*. All the conducting mechanisms hitherto described are represented in *Lepidosiren*, in respect of their situation and connexions, by purely nervous structures. The mechanism consists of a nervous continuum comprising regions of the medulla oblongata and communications involving the sixth aortic arch, the ductus Botalli, the pulmonary artery, the sinus venosus, atria and ventricles of the heart and the pulmonary vein, with bilateral connexions at three (probably segmental) levels. The continuum—or cardiac neural primordium—precedes the general development of the cardiac musculature and forms a nodal nervous complex, to which it appears the whole development of the characteristic form of the heart may be referred as to an organic system of developmental foci.—**George W. McCrea**: An X-ray examination of *d*-mannitol and *d*-mannose. *d*-Mannitol: (see NATURE for Jan. 31, p. 162); *d*-Mannose: unit cell, $a = 5{\cdot}53$ A., $b = 17{\cdot}66$ A., $c = 7{\cdot}59$ A.; space-group, Q^4; calculated density, 1·602 gm. per c.c.; 4 molecules per cell. A manno-pyranose ring structure is probable in the *d*-mannose molecule, and the greatest length of the molecule is along the *c* axis.—**R. B. Mooney** and **H. G. Reid**: The absorption spectra of cyanogen and the cyanogen halides. Measurements are given of the band edges of the cyanogen absorption spectrum in the region 2380-1850 A. The influence of temperature on the relative intensities of the bands has been studied. The long wave-length limits of the regions of continuous absorption due to the cyanogen halides are: CNCl, 2240 A.; CNBr, 2540 A.; CNI, 3100 A. and 2150 A.—**W. O. Kermack** and **W. H. McCrea**: An operational method for the solution of linear partial differential equations. A general method has recently been given by Prof. E. T. Whittaker for the solution of differential equations by definite integrals. A closely related solution is now given, in which a differential operator appears in place of the integration. This may be regarded as a generalisation of Maclaurin's theorem. Certain applications of the theorem, including its application to the theory of generating functions, are discussed.—**H. S. Ruse**: On the definition of spatial distance in general relativity. A mathematical analysis of the problem of defining spatial distance (in a general Riemannian space-time) leads to a definition alternative to that recently obtained from astronomical considerations by E. T. Whittaker. Applied to a Galilean space-time and to the de Sitter world, the formula derived from the new definition yields the quantities hitherto regarded as representing 'spatial distance' in these particular cases.

PARIS.

Academy of Sciences, Oct. 12.—**A. Lacroix**: Obituary notice of Friedrich Becke.—**André Blondel**: Comparison between a cable with distributed constants and a circuit in *T*.—**W. Vernadsky** and **A. Vinogradoff**: The chemical composition of *Lemna* as characteristic of the species. Each species of *Lemna* collected in localities so far apart as the Ukraine and the Baltic region, and in different years, possesses a definite composition which characterises it.—**J. Schokalsky**: A new hypsometric map of the Soviet Union (European part) on the scale of 1/2,500,000.—**Léon Pomey**: New remarks relative to the last theorem of Fermat.—**E. O. Lovett**: A problem of Gambier in the deformation of surfaces.—**Hadamard**: Remarks on the preceding communication.—**B. Galerkin**: The elastic equilibrium of a thick rectangular plate.—**Kourensky**: The fundamental equation of exterior ballistics.—**J. Ph. Lagrula**: The inconvenience of using four stars in the local connexion of two photographs of large field, even when the distance of the centres is considerable.—**Th. V. Ionescu**: Ionised gases and the working of valves with positive grid. In a previous paper the author has shown that the velocity of propagation of waves in tubes containing ionised gas can be calculated, assuming for the gas a definite period of vibration. It is now shown that, taking these vibrations into account, the working of valves with positive grid can be explained, and the formula of Barkhausen obtained.—**F. Esclangon**: A method of measuring an alternating high-frequency magnetic field. The Foucault currents produced are measured by a mercury thermometer. It has been proved that the velocity of heating is proportional to the square of the field strength and to the square root of the frequency.—**B. Demetrović**: Some experiments concerning the reflection of X-rays. Description of experiments proving that the X-rays are strongly reflected by surfaces which form a bad mirror for visible light.—**F. Vlès** and **A. Simchen**: Remarks on the permanganate spectrum.—**J. Gilles**: Quintuplets and triplets of O III.—**E. Herzog** and **G. Chaudron**: The protection by cathode polarisation of iron dipped into aerated saline solutions. Depolarising deposits can be formed by simple aeration of metallic surfaces dipped into saline solutions. These experiments explain why certain metallic additions can exert a protective action on a metal being corroded.—**Georges Arditti**: The oxidation of paraffin oil. A study of the action of air in the presence of various catalysts on paraffin oil at 130° C.—**Mme. N. Demassieux** and **Victor Henri**: The ultra-violet absorption spectra of pure hydrochloric acid and bromine. Hydrochloric acid, prepared by methods commonly regarded as giving a pure product, gives an absorption spectrum in the ultra-violet which varies with different specimens. These differences have been traced to the presence of bromine: a trace of bromine in $10\,N$ hydrochloric acid gives an absorption which is several thousand times more intense than that produced by the same quantity of bromine in water. Whilst chemical methods fail to detect smaller proportions of bromine than 0·001 gm. per litre, the ultra-violet absorption spectrum can detect less than one-tenth of this.—**Augustin Boutaric** and **Raymond Amiot**: Experimental researches on the adhesion of lubricating layers to metals. Plates of various metals (copper, iron, aluminium, and rustless steel) were dipped in oil, allowed to drain for measured times, and the plate then centrifuged at 5000 rotations per minute. A relation between the oil on the plate (p) after a time of draining (t), and the limiting weight after centrifugation was established.—**Picon** and **Cogné**: The study of some sulphides of the rare earths. Description of the preparation and properties of the sulphides of yttrium, lanthanum, cerium, neodymium, and samarium.—**J. Bancelin**: Carbonates of the chromiammines.—**Raymond Paul**: Some pentenyl derivatives.—**C. Le Camus** and **F. de Saint-Just**: Magnetic and electrical observations in the Sahara. Measurements of the magnetic elements and of the atmospheric electrical field were made at Gao, Tanesrouft, and Camp Louis Marin (Hoggar), the two latter being new observation points.—**A. Maige**: Remarks on the subject of the physico-chemical mechanism of the amylogen condensation (in plants).—**O. Duboscq** and **P. Grassé**: The parabasal apparatus and the cytoplasmic constituents of zooflagellæ.—**F. Marceau** and **L. Acolat**: General considerations on the circulation of the arterial and venous blood in three-chambered hearts of vertebrates and the measurement of the degree of mixture.—**L. Lutz**: The soluble ferments secreted by the hymenomycete fungi. Comparison of the anti-oxygen power of tannin and the phenolic constituents of essential oils.—**J. Magrou**, **Mme. M. Magrou**, and **P. Reiss**: Action at a distance and the development of the egg of the sea-urchin. Attempt at an interpretation.—**E. Brumpt**: *Cercaria ocellata*, the cause of dermatitis in bathers, arises from a *Bilharzia* of the duck.—**Georges Bourguignon**: The interpretation of the variations of muscular chronaxy by repercussion, with and without functional troubles.

Diary of Societies.

FRIDAY, November 20.

Royal Society of Medicine (Physical Medicine Section) (at British Red Cross Clinic, Peto Place, N.W.1), at 5.—A. Woodmansey: Catalysis in relation to Mineral Waters.

Physical Society (at Imperial College of Science), at 5.—Dr. F. Lowater: The Band Spectrum of Zirconium Oxide.—W. A. Wood: Lattice-distortion of Cold-drawn Constantan Wire.—Dr. F. Aughtie: (*a*) A Remote Electrically Recording Accelerometer with Particular Reference to Wheel-impact Measurements; (*b*) A Remote Electrically Recording Load-gauge for Wheel-impact Measurements.—Prof. E. V. Appleton and G. Builder: Wireless Echoes of Short Delay.—Prof. Kerr Grant: *Demonstrations:*—A Contrivance for Demonstrating the Law of Errors; a New Type of Surface-tension Meter; and a New Type of Static Electrometer.

Society of Chemical Industry (Liverpool Section) (at University, Liverpool), at 6.—Prof. I. M. Heilbron: Nature's Variations on the Isoprene Theme.

Institution of Mechanical Engineers, at 6.—Presentation of Sixth Report of the Marine Oil Engine Trials Committee.

Society of Dyers and Colourists (at 36 George Street, Manchester), at 7.—C. M. Whittaker: Random Leaves from a Viscose Yarn Dyer's Notebook.

Royal Photographic Society of Great Britain, at 7.—W. L. Shand: Pattern and Design in Pictorial Photography.

Society of Dyers and Colourists (Glasgow Section) (at George Hotel, Glasgow), at 7.15.—H. E. Potts: Patents.

Society of Chemical Industry (South Wales Section) (jointly with Institute of Chemistry—South Wales Section) (at Mayfair Café, Cardiff), at 7.15.—Dr. J. H. Quastel: Dyestuffs and Biological Activity.

Society of Chemical Industry (Glasgow Section) (at St. Enoch Hotel, Glasgow), at 7.30.—Prof. J. C. Philip: The Abstracting of Chemical Literature.

Junior Institution of Engineers, at 7.30.—H. G. Brown: Modern Pressed Brick Manufacture.

Institute of British Foundrymen (Sheffield and District Branch) (at Albany Hotel, Sheffield), at 7.45.—J. E. Hurst: Further Experiments with Air and Oil-hardening Cast Irons.

South London Botanical Institute (323 Norwood Road), at 8.—J. E. Lousley: Plant Parasites (Lecture)

Royal Society of Medicine (Obstetrics and Gynæcology Section), at 8.15.—Dr. Louisa Martindale: Recent Advances in Deep X-Ray Therapy in Gynæcological Conditions.—Dr. B. Solomons: Obstetric Methods at the Rotunda Hospital in 1909 and 1929.

Royal Society of Medicine (Radiology Section), at 8.30.—Discussion on X-ray Diagnosis of Diseases of the Chest.—Dr. S. Melville: Tuberculous and other Non-malignant Conditions.—Dr. P. Kerley: Malignant Conditions.

Royal Institution of Great Britain, at 9.—Prof C. H. Lander: Oil and Petrol from Coal.

Royal Aeronautical Society (Hull and Leeds Branch).—Lt.-Col. W. L. Marsh: Speed in Aviation and what it means.

SATURDAY, November 21.

Royal Institution of Great Britain, at 3.—W. Perrett: The Music of Ancient Greece (1): The Enharmonic Genus.

British Psychological Society (at King's College), at 3.—Rev. H. L. Philp: Frustration of Will Acts.—M. F. Lowe: Blood Distribution during Mental Activity.—*Demonstrations:*—A. G. Caws: Perception of Tachistoscopically Exposed Symbols.—R. Westgate: Effect of Affective Stimuli on Muscular Work.

Institute of British Foundrymen (Wales and Monmouth Branch) (at University College, Cardiff), at 6.30.—Prof. A. A. Read: The Microscope in Metallurgy.

Institute of British Foundrymen (Lancashire Branch—Junior Section) (at Manchester College of Technology), at 7.—A. Hopwood: Non-Ferrous Founding.

MONDAY, November 23.

Electrical Association for Women, at 6.15.—The Healing Effects of Electric Rays.

Institution of Mechanical Engineers (Graduates' Section—London) (jointly with Students' Section of Institution of Civil Engineers), at 6.45 —L. A. Beaufoy: Mechanical Solution of Rigid Frames.

Institution of Electrical Engineers (Informal Meeting), at 7.—R. Grierson and others. Discussion on The Electrical Heating of Buildings.

Institution of Electrical Engineers (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—E. W. Dickinson and H. W. Grimmitt: The Design of a Distribution System in a Rural Area.

Institution of Electrical Engineers (South Midland Centre) (at Birmingham University), at 7.—E. A. Watson: Coil Ignition Systems.

Institute of Chemistry (Leeds Area Section) (Annual General Meeting) (at Great Northern Hotel, Leeds), at 7.15.—At 7.30.—A. R. Tankard and others: Discussion on The Food and Drugs Act, 1928.

Royal Society of Arts, at 8.—H. R. Ricardo: Diesel Engines (Howard Lectures) (1).

Royal Society of Medicine (Odontology Section), at 8.—Prof. L. S. Dudgeon: Vincent's Angina and Allied Affections of Mouth and Throat.

TUESDAY, November 24.

Royal Medico-Psychological Association (at B.M.A. House, Tavistock Square), at 3 —Sir Hubert Bond: Testimonied in his own Bringingsforth (Maudsley Lecture).

Royal Society of Arts (Dominions and Colonies Meeting), at 4.30.—M. Breton: Sericulture in the British Empire.

Royal Society of Medicine (Medicine Section), at 5 —Discussion on Nervous Dyspepsia.

Royal Institution of Great Britain, at 5.15.—Prof. J. B S. Haldane: New Light on the Origin of Species (2).

Institute of Marine Engineers, at 6.—A. E. L. Chorlton: The Work of Akroyd Stuart and the Development of the Oil Engine in which it is carried on (Akroyd Stuart Award Paper, 1930-31).

Institution of Electrical Engineers (London Students' Section), at 6 15.—H. S. Hind: The Recording and Reproduction of Talking Pictures.

Institution of Electrical Engineers (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—R. M. Charley: Recent Progress in Large Transformers.

Institution of Electrical Engineers (North-Western Centre) (at Engineers' Club, Manchester), at 7.—E. W. Dickinson and H. W. Grimmitt: The Design of a Distribution System in a Rural Area.

Royal Photographic Society of Great Britain (Scientific and Technical Group), at 7.—A. J. Bull: How it works in Photography (4): Three Colour Photo-engraving.

Quekett Microscopical Club (at 11 Chandos Street, W.1), at 7.—Gossip Meeting.

Sheffield Metallurgical Association (at 198 West Street, Sheffield), at 7.30.—H. T. Hildage: Works Progress.

Royal Anthropological Institute, at 8.30.—Dr. A. N. Tucker: Sudan Music.

Diesel Engine Users' Association (at Caxton Hall).—H. V. Stead: Diesel Engines for Overseas Work.

WEDNESDAY, November 25.

British Astronomical Association (at Sion College), at 5.

Royal Society of Medicine (Comparative Medicine Section), at 5.—Discussion on Active Immunisation in Virus Diseases.

Eugenics Society (at Linnean Society), at 5.30.—Prof. C. G. Seligman: Race and Temperament.

Newcomen Society for the Study of the History of Engineering and Technology (Annual General Meeting) (at Chartered Institute of Patent Agents, 1 Staple Inn Buildings), at 5.30.—T. B. Hennell: Men or Straw: An Account of Surviving Straw Handicraft.

Institution of Automobile Engineers (Manchester Centre) (at Engineers' Club, Manchester), at 7.—B. G. Robbins: The Training of Young Automobile Engineers.

North-East Coast Institution of Engineers and Shipbuilders (Graduate Section) (at Mining Institute, Newcastle-upon-Tyne), at 7.15. —Angus Watson: The Adventure of Life.

Leicester Literary and Philosophical Society (Chemistry Section) (at Museum, Leicester), at 7 30 —H. L. Long: Science in the Modern Laundry (Presidential Address).

Royal Society of Arts, at 8.—G. G. Blake: An Investigation throwing New Light upon Duplex Therapy and other Electro-medical Applications.

British Psychological Society (Industrial Section) (at Red Lion Restaurant, Red Lion Square), at 8.—J. Blackburn: Some Obstacles to the Determination of the Effect of Practice upon the Differences between Individual Performances.

British Psychological Society (Medical Section) (at 11 Chandos Street, W.1), at 8.30.—Dr. C. S. Read: Out-Patient Psychiatry.

THURSDAY, November 26.

Institute of Metals (Birmingham Local Section) (at Chamber of Commerce, Birmingham), at 7.—W. F. Brazener: The Casting of Tough Pitch Copper.

North-East Coast Institution of Engineers and Shipbuilders (Tees-Side Branch—Graduate Section) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7 30.—F. Whitfield and others: Discussion on Internal Combustion Engines.

Royal Society of Medicine (Urology Section), at 8.30.—Clinical Pathological Meeting.

British Psychological Society (at 55 Russell Square, W.C.1), at 8.30. —Prof. T. H. Pear: Suggested Parallels between Modern Speech and Clothing (Lecture).

Institute of Brewing (North of England Section) (at Midland Hotel, Manchester).—W. A. Riley: Problem of Bottling.

FRIDAY, November 27.

Andersonian Chemical Society (at Royal Technical College, Glasgow), at 8.15.—Prof. J. Kendall: Ionisation Theories: Old and New.

Royal Astronomical Society (Meeting for Geophysical Papers), at 4 30. —Dr. H. Jeffreys: On the Variation of Melting-Point within the Earth. —R. Stoneley: The Thickness of the Continental Layers of Europe.—A. W. Lee: The North Sea Earthquake of Jan. 24, 1927.

North-East Coast Institution of Engineers and Shipbuilders (at Mining Institute, Newcastle-upon-Tyne), at 6.—Dr. F. H. Todd: Some Measurements of Ship Vibration.

Manchester Literary and Philosophical Society (Chemical Section) (at 36 George Street, Manchester), at 7.—J. M. Preston: Textile Microscopy.

Institution of Mechanical Engineers (Informal Meeting), at 7.—Dr. W. A. Scoble and others: Discussion on Wire Ropes, their Selection and Use.

Junior Institution of Engineers, at 7.30.—D. W. McJannet: Progress in the Design and Construction of Static Transformers.

Royal Institution of Great Britain, at 9.—Sir Alfred Ewing: The Work of Sir Charles Parsons.

SATURDAY, November 28.

Royal Institution of Great Britain, at 3.—W. Perrett: The Music of Ancient Greece: The "Orestes" Fragment.

PUBLIC LECTURES.

FRIDAY, November 20.

University College, Dundee, Scientific Society (at Dundee), at 4.30.—Prof. J. Read: An Organic Chemist looks at Australia.

Institute of Chemistry, at 8.—Dr. J. V. Eyre: Recent Advances in the Fermentation Industries (Streatfeild Memorial Lecture).

SATURDAY, November 21.

Horniman Museum (Forest Hill), at 3.30.—H. St. George Gray: The Romans in the South of England.

MONDAY, November 23.

University College, at 5.30.—Prof. G. Dawes Hicks: The Philosophy of Religion (Hibbert Trust Lectures). (Succeeding Lectures on Nov. 30, Dec. 7 and 14.)

St. Leonard's School, St. Andrews, at 8.—Prof. J. Read: Alchemy and the Alchemists.

TUESDAY, November 24.

Goldsmiths' Hall, E.C., at 4.30.—Dr. H. H. Dale: Biology and Civilisation (Norman Lockyer Lecture).

University College Hospital Medical School.—Dr. R. T. Grant: The Pathology of Endocarditis. (Succeeding Lectures on Dec. 1 and 8.)

WEDNESDAY, November 25.

Royal Institute of Public Health, at 4.—D. Lees: Venereal Diseases in City Life.

King's College, London (at 40 Torrington Square, W.C.1), at 5.30.—Dr. W. Borowy: Poland and its Civilisation in the Middle Ages.

Imperial College of Science and Technology, at 5.30.—Prof. E. A. Milne: The Theory of Stellar Structure. (Succeeding Lectures on Nov. 26 and 27.)

London School of Economics and Political Science, at 6.—P. T. Lloyd: The Form *versus* the Machine in Office Records.

Belfast Museum and Art Gallery, at 8.—Dr. K. G. Emeléus: Atoms, Electrons, and X-Rays

THURSDAY, November 26.

Science Museum, South Kensington (in connexion with Exhibition of Modern Glasses), at 4 45.—R. W Clark: The Supreme Glass: Fused Silica.

Royal Institution, at 5.—A. Whitaker: Physics in Sound Recording (Institute of Physics Lectures on Physics in Industry)

Bedford College for Women, at 5.15.—Sir William Beveridge: The Meaning of Purchasing Power (Stevenson Lecture).

Institution of Civil Engineers, at 6.—Prof. C. E. Inglis: Vibrations in Railway Bridges and Impact Allowances (Armourers' and Brasiers' Company Lectures). (Succeeding Lectures on Dec. 3 and 10.)

Battersea Polytechnic, at 7.—Dr. H. Phillips: The Walden Inversion: The Mechanism of the Substitution of Groups in Saturated Organic Compounds (2).

FRIDAY, November 27.

London School of Economics and Political Science, at 5.—Prof. L. Hogben: Genetic Principles in Medicine and Social Science. (Succeeding Weekly Lectures in Michaelmas Term and in Lent Term beginning on Jan. 15.)

SATURDAY, November 28.

Horniman Museum (Forest Hill), at 3.30.—Miss I. D. Thornley: Pilgrims of Medieval England.

CONGRESS.

Friday and Saturday, November 20 and 21.

Public Works, Roads, and Transport Congress (at Royal Agricultural Hall).

Friday, Nov 20, at 11 a.m —H. R. Lintern: A Philosophy of Civil Engineering Training.
H. R. Lintern: Considerations affecting Highway Department Organisation.
At 3.—F. H. Osmond-Smith: Suicide in Agriculture.
H. T. Tate: Statutory Small Holdings.
T. G. Ellis: The Economic Principles which should govern the Equipment of Small Holdings.
H. Davis: Street Lighting in relation to Transport

Saturday, Nov. 21.—S. C. Baggott: The Collection and Disposal of House Refuse.

EXHIBITION.

Thursday and Friday, November 26 and 27.

Scientific Exhibition (at 16 Royal Terrace, Edinburgh), 5.30 to 9.

SATURDAY, NOVEMBER 28, 1931.

Geological Survey of India.

THE Geological Survey of India has won a well-deserved reputation as one of the leading surveys of its kind in the world. An unusually high proportion of its officers, past and present, have attained international fame as geologists, and in keeping with this fact its publications rank amongst the most important of those which make genuine contributions to the advance of geological knowledge. It is therefore both surprising and alarming to find, in connexion with the financial retrenchment imposed upon the Government of India by the necessity of balancing its budget, that serious proposals have been put forward to reduce the staff and salary scales of the Survey to an extent that would be nothing short of disastrous.

In our issue of Nov. 14 we commented on the retrenchment proposals which affect the Zoological Survey of India, relative to which Sir C. V. Raman has issued a timely Memorandum. In a similar Memorandum on the Geological Survey of India, Sir C. V. Raman discloses the fact that it has even been urged that the Survey could be permanently or temporarily closed down. Another proposal would reduce the personnel to a nucleus of eight members. The Retrenchment Advisory Committee, however, has finally recommended the retention of the director, three superintendents, and ten assistants; three superintendents and twelve assistants being dispensed with.

All of these disturbing proposals seem to be based on the extraordinary assumption that as the Survey has already been in existence for eighty years it has begun to outlive its usefulness. Nothing could be further from the truth. Sir C. V. Raman clearly shows in his Memorandum that the need for intensive geological investigation is steadily increasing and that the present activities of the Survey are actually insufficient to meet the demands of a territory so vast as that of the Indian Empire. He claims with justice that many of the mineral and associated manufacturing industries of India owe their present status to the discoveries of the Survey, and he points out that the royalties and income-tax derived from these sources can legitimately be claimed as a direct financial return for the money spent on its maintenance. It is also shown that the advisory work of the Survey results in the saving of large sums every year and in the prevention of waste and the avoidance of disaster to life and property that would otherwise be, for the most part, inevitable.

An alternative scheme of reorganisation suggested by Sir C. V. Raman involves considerable reductions in salaries on an increased staff of one director, forty geologists (superintendents being regarded as unnecessary), one chemist, one artist, and six museum assistants. It must not be overlooked, however, that the traditionally high standard of the Survey is in no small measure attributable to the attractive conditions offered by the service. Hitherto the Survey has recruited its officers from the most promising of our post-graduate geologists. At present a geologist enters at Rs. 400 and rises in sixteen years to Rs. 1200, with a reasonable chance of promotion to the grade of superintendent at Rs. 1500 to Rs. 2000. On the proposed scale a geologist would enter at Rs. 300 and, after passing an efficiency bar at Rs. 750, rise to Rs. 1000 in eighteen years. It cannot be anticipated that a scale so drastically reduced will continue to maintain the Survey at its wonted level of achievement.

Sir C. V. Raman makes a very good point in directing attention to the cost of other leading geological surveys. The United States and Canada, countries comparable with India in the nature and magnitude of the problems requiring attention, expended respectively in 1929–30, 4,212,294 dollars and 705,325 dollars. We may add that the U.S.S.R. in 1928–29 devoted £1,359,000 to the activities of the Russian Geological Committee. That the results have justified this unprecedented expenditure and that geology is appreciated at its true worth in that much criticised land would appear to be shown by the official announcement that in 1932–33 more than three thousand field workers will take part in some eighteen hundred expeditions at a budgeted cost of £5,918,000.

Can it be seriously pretended that India can afford to dispense with an efficient geological service? Sir Albert Kitson stated the case unanswerably in his presidential address in 1929 to Section C (Geology) of the British Association on "The Utility of Geological Surveys to Colonies and Protectorates of the British Empire". Unfortunately, recent events have driven home the bitter truth of his comment that such surveys have benefited the British Dominions "immeasurably more than is yet realised by them".

We have discussed the position as regards the Zoological and Geological Surveys of India. Drastic proposals have also been made by the Retrenchment Advisory Committee for reducing the expenditure of other scientific departments. Accepting the fact that the Government of India, like most other governments, is faced with a grave financial crisis, we may take exception to the steps which have been adopted to secure recommendations for economies. When a business firm is faced with such a situation, the usual procedure is to call a conference of departmental heads and ask them to prepare a scheme to enable the firm to carry on over the crisis with the least possible damage to the efficiency of the organisation. The Government of India has sought advice from an able body of men who, however, know little or nothing of the highly specialised activities of the scientific departments of the Indian Empire. This raises again the problem to which we have repeatedly referred in these columns, namely, the alleged incompetence of scientific workers in administration. It is safe to say that, had anyone familiar with the methods and achievements of science been included in the personnel of the General Purposes Sub-Committee of the Retrenchment Advisory Committee, its present report would never have been published unchallenged.

The Internal Combustion Engine.

(1) *Power and the Internal Combustion Engine.* By Prof. W. E. Dalby. Pp. viii + 280. (London: Edward Arnold and Co., 1931.) 18*s*. net.

(2) *The High-Speed Internal-Combustion Engine.* By Harry R. Ricardo. New edition. Pp. vi + 435. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1931.) 30*s*. net.

WITH two newly issued volumes on the internal combustion engine lying on the table, one by Prof. Dalby and the other by Mr. Ricardo, the reviewer expected new light on a subject at once important, interesting, and strangely elusive. The new light is rather disappointing. Where one hoped to find a general illumination on an ordered scene, one finds in the former book much attention given to the author's special interests, and in the latter just as good a presentation of modern knowledge as a very busy investigator, with a somewhat less easy command of English than the best, can give time to produce. Perhaps it would be fair to add that a few years ago books of this kind would have been read with minds less critical than those of to-day, and that if one man more than another is responsible for this, the 'blame' may be put on Sir James Jeans, who, whether in the simple "Stars in their Courses" or the comprehensive "Astronomy and Cosmogony", has shown us how lucidly and forcefully information on natural phenomena of great complexity may be presented.

(1) In Prof. Dalby's book, with the broad title of "Power and the Internal Combustion Engine",

one expects to find a unitary conception of the engine and its path of development to date. This, however, is scarcely attained. The general scheme adopted is to proceed from the ' working agent ' to mixtures and fuels, thence to the engine itself and the ' Dalby diagram ', followed by the suction gas plant, the petrol engine in detail, and finally heat flow in its effect on design. The author has a curious way of giving authority for his statements and figures : thus, in his first chapter the number of molecules in the cubic centimetre is given on the unexpected authority of the "Encyclopædia Britannica" —scarcely an original source ; and a few pages later he includes, without a smile, under the heading of " some gases whose molecular weights are given " elsewhere, " the Liverpool Gas Company ". The author endeavours to state all measurements in engineers' units even when dealing with the work of chemists and physicists. This makes the reading somewhat heavy, and it does not help the student when he has to refer to books on chemistry and physics.

As an occasion for desultory—but pleasant—wandering there is much to be said in the book's favour, and in fairness to the author it should be mentioned that the preface contains the warning that " to read Chapter i. involves knowledge of Chapter iii.", though somewhat unexpectedly it explains also that " to read Chapter iii. involves some knowledge of Chapter i." Such a book is scarcely for the training of students. What would a student make, for example, of the information that " the weight of vapour or gas which will enter a given volume at a given temperature is the same whether the space be a vacuum or contains other gases " ? Is he to measure the temperature of a vacuum, and if so, how ? In another place the author seeks to explain the simple ratio " 1/4 per cent by volume " by the elucidation that it is " less than half a fluid ounce per gallon ".

The author sums up towards the end of the book that " probably no invention in the history of man has at one and the same time so much increased his comfort and so much increased his anxieties, as this small, light and efficient prime mover—the petrol engine ". It is evident that these anxieties are shared by the engineer, for the last sentence in the book gives warning of the danger of " cracked liners, cracked pistons and cracked cylinder heads ".

The book contains, or gives references to, much of the best work which has been done on this subject in the last twenty years, and one cannot but be grateful to any author who helps, as Prof. Dalby does, to make such work more readily accessible to the investigator.

(2) Mr. Ricardo's book is in very interesting contrast to Prof. Dalby's. It is written by a man with a synthetic brain, and if he were not so occupied with his important research work he could probably write the best book on this subject that has ever been written. The present volume is, however, a reissue, after eight years, of an earlier book now partly out of date. In the first edition there were errors common to most first editions, and it was to be expected that the issue of a new edition would have afforded an opportunity to correct them, but this expectation is not entirely fulfilled ; nor has the chance been taken to correct certain statements and definitions which contain so much scientific error, as presented, as make it impossible to pass them by. Examples are seen in the author's strange use of ' internal energy ' and his loose way of speaking of heat energy in fuels. Certainly the definition of ' total internal energy '—on p. 21 —is wrong and should be deleted. In the same chapter the reader is told that the heat value of a volatile fluid has no relation to the power output—again quite untrue and the blue pencil needed. The reader may know what the author means, but that is no excuse for the use of incorrect language ; and those who do understand the meaning will scarcely be those who need to read the book. Nor is it wise to mix both Centigrade and Fahrenheit scales of temperature. Indeed, in a book not intended for popular consumption there can be little excuse for using the latter at all.

The author's remark on p. 40 that the reaction velocity is trebled by a three per cent rise in temperature for all hydrocarbon fuels, probably refers to the work of Tizard and Pye. If it does, is the figure ' three ' correct, and was it shown by them to apply to all hydrocarbon fuels ?

As regards the new sections on detonation, it is fair to state that a general result which has emerged in recent years is that detonation is mainly a chemical problem which cannot well be explained by treating the explosive mixture in bulk ; there is no mention, however, in Ricardo's treatment of detonation of Callendar's and Egerton's theories and the idea of chain reactions. Mention of these is, it is true, made later when the author deals with the action of metallic dopes, but this rather suggests that these theories do not apply to the initiation of detonation in general but are only of interest in connexion with ' dopes '.

Nevertheless, the reviewer considers the book the best there is in the English language on the present position of research work on the internal combustion engine. At the moment this research work is proceeding on healthy lines. It is chiefly guided in Great Britain by the Engine Sub-Committee of the Aeronautical Research Committee, the Air Ministry providing most of the funds for such researches, whether undertaken at the aero engine builders' works, at the Government research establishments, or in the research laboratory of Mr. Ricardo himself. All this research work is published, when it has reached a suitable stage, in the Reports and Memoranda Series of the Aeronautical Research Committee. So much work is now in hand in Great Britain alone on compression ignition types, two-stroke cycles, sleeve-valve operation, fuel injection, supercharging, and 'boosting', that any summary of it all issued to-day must speedily become out of date. It is too much to expect, therefore, that Mr. Ricardo's volume can give an entirely synchronous account of the present position, but it certainly comes much nearer to doing so than does the writing of any single author in Great Britain or elsewhere.

Studies in Immunity.

Medical Research Council. A System of Bacteriology in relation to Medicine. Vol. 6. By J. A. Arkwright, S. P. Bedson, C. H. Browning, H. R. Dean, A. T. Glenny, P. Hartley, J. C. G. Ledingham, H. B. Maitland, R. Muir, H. L. Schütze, W. M. Scott, D. B. Steabben, J. W. Trevan. Pp. 538. (London: H.M. Stationery Office, 1931.) 21*s.* net.

THE literature on immunity has almost got beyond the limit of the capacity of any one worker, and this volume on the "System of Bacteriology" will be welcomed not only by laboratory workers, but also by all interested in this difficult but fascinating subject. The volume stands out as one of the best in the "System", and each chapter is written by a worker who has an intimate experimental knowledge of his subject. There is an adequate summary of most of the important papers which have been published, and the writers have given their own views, based largely on their own experimental work, but have, at the same time, dealt very fairly with the writings of other experimenters in the same field.

Chap. i., on "Bacteria in Relation to Disease", is a necessary introduction, and is concise, well written, and accurate. A subject such as immunity, which is still based to a considerable extent on theory, has had associated with it various terms which were useful but the meanings of which were not at all definite. We are glad to see in this chapter a suggestion that some of these, such as endotoxin, leucocidin, aggressin, have served their purpose, but have lost their usefulness and should be avoided. This will be a difficult task to accomplish, and it is significant that the succeeding writers have not followed, even one step, in this suggested path. A brief account is given of the very important and difficult subject of the virulence and antigenic complexity of bacteria in its bearing on the genesis and extinction of epidemics.

Chap. ii., on "Natural Immunity", by Prof. Ledingham, is very detailed, but so well written that the detail does not in any way detract from its interest. There are many points of great importance not merely mentioned but discussed. In the first place, he deals with the normal defence mechanisms, such as bactericidal and hæmolytic action, opsonins, leukins, etc. He emphasises the fundamental importance of phagocytosis, and then he discusses the modifications which may be induced on these normal and 'non-specific' substances found in the body by the parenteral injections of proteins, etc., and by various physical and chemical agents, such as ultra-violet light, fatigue, and certain reflexes, such as sound. The bearing of nutritional factors is discussed, especially in relation to the antibody-forming mechanism and the resistance to spontaneous and induced infection. The natural resistance to various infections, the problem of local immunity, and much of the recent work on the reticulo-endothelial system are dealt with very thoroughly. The whole chapter bristles with interesting facts.

Chap. iii., on the "Production of Active Immunity to Bacterial and Virus Infections", is by Ledingham and Schütze. They deal with the work of Jenner, the early work of Pasteur, and the modification of their methods, and follow this up with the whole subject of bacterial vaccines, dealing with the work on typhoid, cholera, plague, etc., and the virus diseases, such as rabies, foot-and-mouth disease, distemper. A very interesting discussion is given on immunity as influenced by recent knowledge of bacterial antigens, and it is shown how our views have been modified by the investigations on the subject of the flagellar and somatic antigens.

Chaps. iv. and v. deal with toxins, and relate largely to chemical and physical problems. They are written by experts on the subject, and will prove of great value to laboratory workers, but their interest will be mainly for such.

In Chap. vi., by Prof. Browning, the antigens and antibodies are discussed. Among the many interesting points there are some which are perhaps not sufficiently recognised by vaccine therapists.

We are told that, as a rule, antigens introduced into the stomach are either destroyed by the digestive ferments or fail to be absorbed. Thus, the oral administration, though not rejected altogether, is regarded as generally useless. The transference of antibodies from mother to fœtus occurs, apparently, only in some species of animals and not in others. The whole chapter will repay careful reading, and may be regarded as a standard work on the subjects.

Chap. vii., by Dr. Hartley, gives a very full account of the effect of physical and chemical agents on the properties of antigens and antibodies. This study of the chemistry of bacterial cells and bacterial products is still very imperfect, though the work of Hartley himself and those whose investigations are recorded in this chapter have done something to clear up doubts and difficulties.

Chaps. viii., ix., and xi., on "Anti-bacterial Sera, Hæmolytic Action, and Opsonic Action", are by Prof. Muir, with certain minor sections by other authors. These chapters, with Chap. x., by Browning, and xii., by Arkwright, are, we think, the most important and valuable in the volume. They cover the whole ground with great success. They are well written, and are clearly the work of men who not only have an intimate working knowledge of the subjects with which they deal, but also have the faculty of conveying their knowledge to others. There are many points to which one would like to refer, but space will not permit.

In Chap. xiii., Dean deals with the precipitin reaction in considerable detail; discusses the source of the precipitate, its specificity and practical application, and its relation to other serum reactions. This chapter will, we hope, have the effect of clarifying the somewhat hazy views which are held by many people on precipitins. It is a chapter of very great value.

Chap. xiv. is a brief critical survey of antiferments and defensive ferments, by Prof. Browning, in which he emphasises the fact that many of the observations on these subjects have not led very far in the investigation of disease.

Chap. xv. is an excellent and fairly exhaustive review of the work on anaphylaxis and serum sickness and allergy. There are many practical points concerning the therapeutic uses of serum, and Dr. Scott emphasises the dangers and uncertainties, especially of desensitisation. This is an extremely useful contribution both to the laboratory worker and the clinician.

Miss Steabben in Chap. xvi. gives a short survey of immunological problems in their relation to colloid chemistry, and in Chap. xvii. Prof. Browning has given a very clear summary of the value of chemo-therapy particularly in protozoal infections, though he also deals with antiseptics in a limited field in bacterial infections.

We heartily welcome this volume as a really valuable and up-to-date contribution. It should find a place in every bacteriological laboratory and in the library of every medical practitioner.

J. M. Beattie.

Ore-Minerals and the Microscope.

Lehrbuch der Erzmikroskopie. Von Prof. Dr. Hans Schneiderhöhn und Prof. Dr. Paul Ramdohr. Band 2. Pp. xii + 714. (Berlin: Gebrüder Borntraeger, 1931.) 72 gold marks.

Erzmikroskopische Bestimmungstafeln: Anhang zum Lehrbuch der Erzmikroskopie. Von Prof. Dr. H. Schneiderhöhn und Prof. Dr. P. Ramdohr. Pp. 47. (Berlin: Gebrüder Borntraeger, 1931.) 3·80 gold marks.

It would be difficult to over-estimate the value of the contributions to our knowledge of rocks and rock-forming minerals that have resulted from the adaptation of the microscope to petrographical research. The technique of rock examination with the polarising microscope, evolved since the pioneer work of H. C. Sorby, has long been so effective as to make the instrument indispensable to the petrographer.

Naturally, this technique has been focused in the main upon the examination of the transparent minerals—principally silicates—that are the chief constituents of ordinary rocks. Of late years, however, with a growth in the study of mining geology, and especially in view of the remarkable results that have been obtained in the investigation of polished surfaces of metals with the metallographic microscope, increased attention has been paid to the opaque minerals which, while frequently occurring as minor components of common rocks, enter so largely into the constitution of those highly specialised rocks, the metalliferous ores.

As a result a new mineralogical technique, involving the systematised use of reflected instead of transmitted light, is being rapidly developed, and promises eventually to be as serviceable in the study of ores as the old has been in that of rocks. This technique, similar to that of metallography, is variously known as mineralography, mineragraphy, chalcography, and ore-microscopy, but still awaits an appropriate designation.

The application of metallographic methods to the study of opaque minerals began in America soon after the opening of this century, the names of

Campbell, Murdoch, Davy, and Farnham being especially associated with early publications. Good progress was made by these workers both in the methods of preparing polished surfaces of the complex mineral aggregates so often presented by ore-specimens, and in the optical identification of a wide range of opaque minerals difficult to distinguish from one another microscopically. In the course of time the possibilities of work along these lines were realised by mineralogists of other nationalities, and during the last decade contributions of great value have been made by Schneiderhöhn, van der Veen, Orcel, and others in Europe. There have also been numerous recruits in the United States and Canada, and in most laboratories in which ore research is undertaken, investigation by this method is becoming standard practice.

At first the microscope employed differed in no essential from that of the metallographer. Ordinary, that is, unpolarised, light was used, the determination of mineral species being based upon such simple criteria as colour, hardness, cleavage, and so on; and upon micro-chemical reactions obtained with a selected series of etch-reagents. While the data so obtained were in many cases satisfactory, they often proved insufficient for unequivocal identifications, and the need was felt for additional means of diagnosis. The principal innovations of recent years have been designed to provide such extra data, and have consisted of ingenious modifications in the ore-microscope to permit of the accurate measurement of the reflecting power of the various opaque minerals, and of the examination of polished surfaces in polarised as well as in ordinary light.

These refinements have added greatly to the effectiveness of ore-microscopy and to the amount of information it is able to supply. The reflecting power, observed either visually or by means of a photoelectric cell, promises to provide a quantitative factor of great discriminative value. The examination in polarised light, besides giving characteristic reflection-pleochroism in many cases, yields interference effects—reminiscent of the polarisation colours and extinctions shown between crossed nicols by transparent minerals—from which important diagnostic data as to crystallisation, twinning, and so forth may be deduced. As adapted for these additional observations, the ore-microscope is rapidly acquiring distinctive peculiarities, and there can be little doubt that further modifications, making for still greater effectiveness, will be introduced in the near future.

Pre-eminent among those who have helped in the building up of this new branch of mineralogical research is Dr. Hans Schneiderhöhn, formerly of Giessen, now of Freiburg i. Br., who first became interested in it while engaged on the ore-fields of south-west Africa. After returning to Germany, Schneiderhöhn published, in 1922, his "Anleitung zur mikroskopischen Bestimmung und Untersuchung von Erzen und Aufbereitungsprodukten"—an admirable treatise which has since been a standard work of reference. The rapid developments of the last decade, however, have made a fuller and up-to-date presentation of the subject desirable, and this, under the simplified title, "Lehrbuch der Erzmikroskopie", he is now producing in collaboration with Dr. Paul Ramdohr of Aachen. This much-enlarged work is to consist of two volumes and a supplement. The second volume and its supplement have already appeared and are now under review, while the first volume of the complete work, the authors hope, will be available shortly.

The first volume will deal with general principles, apparatus, and technical procedure. The second is descriptive of the minerals met with in ores, no fewer than two hundred species being considered in detail. These are classified on a chemical basis, and include besides the ore-minerals, whether opaque or not, most of the common gangue-minerals also. A uniform system of description is adopted covering composition, physical characters, polishing properties, colour, reflecting power, polarisation effects, etch-reactions, occurrence and genesis, etc. There are nearly 250 admirable reproductions of photomicrographs, and an indication of colour effects observable with or without polarised light is given in a number of beautifully reproduced colour-prints. The supplement—"Erzmikroskopiche Bestimmungstafeln"—consists of an ingenious set of tables for the practical identification of the minerals described by a comparatively simple system of physical, optical, and chemical tests applicable under the microscope. It is put up in the form of a booklet convenient for use in the laboratory.

The preparation of this ambitious publication has obviously entailed much time and labour. The authors state that they have been engaged upon it for eight years, and that in the course of their work they have made and investigated some six thousand polished surfaces of ores from all parts of the world. The volumes when finished will constitute the most complete treatment of the subject ever attempted, and will be invaluable to all who have to investigate ores with the microscope. C. G. C.

Short Reviews.

A Hand-Book to the Flora of Ceylon: containing Descriptions of all the Species of Flowering Plants indigenous to the Island, and Notes on their History, Distribution, and Uses. By Henry Trimen. Published under the Authority of the Government of Ceylon. Part 6: *Supplement.* By A. H. G. Alston. Pp. vi + 350. (London: Dulau and Co., Ltd., 1931.) 30*s.* net.

PENDING a complete revision of the flora of Ceylon, Mr. Alston, lately systematic botanist in the Agricultural Department in that island, has done valuable service in publishing the volume under review. His aim has been twofold: first, to bring in additional matter with regard to a few new species and a number of known species which had been omitted, for one reason or another, from Trimen's "Hand-Book to the Flora of Ceylon", with the appropriate additions to the keys to the families and genera; secondly, to bring to notice nomenclatural changes due to research and to altering concepts of generic and specific limitations.

In connexion with the latter aspect, it is not obvious why the author has rejected certain views of other botanists; for example, the substitution of *Nervilia* for *Pogonia* and *Platanthera* for a section of *Habenaria*, both of which have been accepted by Schlechter, among other authors. Further, it is not permissible, as apparently Mr. Alston thought at the time (the introduction is dated March 20, 1928), to substitute *zeylanicus* where an author has used the form *ceylanicus*; the original spelling must be respected. Nor can these two orthographic variants be valid in the same genus, as the reference to them seems to indicate. A number of typographical errors have escaped detection.

Tamil names taken from the "Flora of the Presidency of Madras" have been incorporated. It is not stated whether these names have been tested in Ceylon. Vernacular names are often very local and Tamil names are apt to vary from district to district in the Tamil country; thus, so widespread and well-known a tree as *Dalbergia latifolia* Roxb. is known as *Iti* in Coimbatore and is called *Eravadi* in Madura and Tinnevelly.

The work will be of great assistance in the revision of the flora of Ceylon which, we believe, is contemplated in the near future.

We Indians: the Passing of a Great Race. Being the Recollections of the last of the Great Indian Chiefs, Big Chief White Horse Eagle, as told to Edgar von Schmidt-Pauli. Translated by Christopher Turner. Pp. 256. (London: Thornton Butterworth, Ltd., 1931.) 10*s.* 6*d.* net.

THIS interesting document is transcribed from the narrative of a great chief of the Osage tribe of Colorado, who it is claimed, not without some sort of corroboration, had attained the age of one hundred and seven years at the time of his narrative. It sketches the life of the Indian of the south-western United States in the earlier half of the nineteenth century, before the buffalo had disappeared and white settlement had restricted the Indian hunting grounds. It also outlines the events which later led up to the defeat of Custer in 1876 and the great peace treaty which, in the view of the narrator, was the death-blow to the Indian.

The Big Chief's claim to the memory of posterity will rest almost equally on the facts that he, as representative of the Indians, buried the hatchet under the steps of the White House at Washington, and as a young man rescued from a massacred emigrant train and brought up with his own children an infant who afterwards became 'Colonel' William Cody, better known as 'Buffalo Bill'. The narrative, which is not without naïveté, has a certain importance as giving the Indian point of view on a number of historical events, though, not unnaturally perhaps, little stress is laid on Indian aggression. The Bureau of Indian Affairs is criticised in strong terms and not without cause.

A History of Surnames of the British Isles: a Concise Account of their Origin, Evolution, Etymology, and Legal Status. By C. L'Estrange Ewen. Pp. xx + 508. (London: Kegan Paul and Co., Ltd., 1931.) 25*s.* net.

THERE is perhaps room for a new history of British surnames since Bardsley and Harrison published their works on the subject. Mr. Ewen has given his history a wider scope than Bardsley and has brought into use much new material. Obviously the "History" has been a labour of love, and there is an inclination to overload it with matter, industriously collected, which has not much direct bearing on the subject in hand and is not always culled from the best authorities. Apart from this criticism, however, Mr. Ewen has given us a work which will be of considerable value to the genealogist and to a lesser extent to the anthropologist. Although the history of personal names has not the scientific value of its sister study of place names, yet much can be learnt by a cautious use of it to show the migrations of races and the settlements of groups of immigrants from other lands, the prevalence of industries in particular districts and the distribution of dialect. But the mobility of the human race and the change of surnames necessitate the greatest care in its use for these purposes. Mr. Ewen has recognised this difficulty and so has wisely emphasised the genealogical value of his study. Of not the least importance is the bibliography given at the end of the volume, which appears to be most comprehensive.

The Spore Ornamentation of the Russulas. By Richard Crawshay. Pp. 185 + 48 plates. (London: Baillière, Tindall and Cox, 1930.) 12*s.* 6*d.* net.

Russula is one of the more easy genera of Hymenomycetes to recognise, but one of the more difficult to classify into species. The spores of *Russula* are ornamented with minute tubercles or warts, sometimes joined together by lines, and the disposition of this ornamentation is used by Mr. Crawshay as an accessory character in the specific classification of the genus. The spores themselves, however, are only a few micromillimetres in length, and the differences in the surface markings are so slight that it would, in many cases, need an experience as intensive as that of the author himself to distinguish them.

The book seems to be directed to the serious amateur possessing a compound microscope, and the first four chapters contain somewhat elementary accounts of microscopic optics, photomicrography, and micrometry. The main portion of the book consists of a useful dichotomous key to the genus, notes on certain species, and forty-six plates of spore drawings, as well as colour charts for spore-deposits and gills. There is an introduction by Bataille.

Apart from its value as a guide to the genus *Russula*, the work is important as marking a step in the endeavours of systematic mycologists to base the specific classification of Hymenomycetes upon something more objective than colour, feel, taste, and smell. W. B. B.

Edward Carpenter: in Appreciation. Edited by Gilbert Beith. Pp. 246 + 2 plates. (London: George Allen and Unwin, Ltd., 1931.) 7*s.* 6*d.* net.

A Heathen's Thoughts on Christianity. By E. Upasaka. Pp. 92. (London: The Pioneer Press, 1930.) 1*s.*

A BRIEF notice may cover various books either by reason of their sympathy or their mutual antagonism. So, in the present instance, in the late Edward Carpenter was encountered a man of strong individuality who grew into a life of practical socialism, surrendering for its attainment a curacy and holy orders, but by no means surrendering the essentials of a religious life. He was, peculiarly, one with many friends and no enemies, though not everyone could approve his views. This "Appreciation" contributed by a few friends bears eloquent testimony to his sterling qualities; his own farewell (written some years prior to his death, to be read from the graveside) is a fitting conclusion. His views upon "A Heathen's Thoughts" would have been welcome as an antidote against its virus. The author has obviously a right to his opinions, nor can he properly be charged with blasphemy where he has no religious belief. But it is a grievous error wilfully to shock the religious beliefs of others, and this book is one which, whilst it can do no good, may conceivably do harm. The 'higher critics' may note that biblical history is worthily championed to-day by those who support their arguments on logical foundations. P. L. M.

Die Nordsudetische Dyas: eine stratigraphisch-paläogeographische Untersuchung. Von Prof. Dr. Hans Scupin. (*Fortschritte der Geologie und Paläontologie,* Band 9, Heft 27.) Pp. viii + 246 + 4 Tafeln. (Berlin: Gebrüder Borntraeger, 1931.) 30 gold marks.

THIS memoir contains the results of a detailed stratigraphical and palæogeographical investigation of the Permian of the region to the north of the Riesengebirge in Silesia. The succession, reaching from the Middle Rothliegendes to the Upper Zechstein, is subdivided on palæoclimatic evidence. The history of the struggle between deepening and filling-up at the margins of the sinking Variscan land provides an interesting study in palæogeography. The memoir closes with an account of the Zechstein copper ore of the district, which is shown to be stratigraphically and mineralogically distinct from the famous Mansfeld Kupferschiefer. It is considered to have been formed by the action of copper sulphate solutions, derived from the weathering of basic igneous rocks, on the calcium carbonate of the Zechstein sea—a conclusion showing the importance of palæogeography in the elucidation of syngenetic ore-deposits.

Mental Nursing (Simplified). By O. P. Napier Pearn. Pp. viii + 304. (London: Baillière, Tindall and Cox, 1931.) 5*s.* net.

DURING the last decade great progress has been made in the nursing of the mentally afflicted. This most difficult branch of nursing in many ways requires more attention and training than its sister branches, due to the fact that the mental side is the more important and is a really difficult subject to understand. Dr. Pearn in his "Mental Nursing (Simplified)" has in many ways made the path of the mental nurse easy. He gives many interesting little artifices for remembering difficult things, and the nurse who knows this book well before he or she begins the familiar "Red Book" of the Royal Medico-Psychological Association will find the latter book a much easier proposition than is usually the case. The subject matter throughout is extraordinarily well set out, following the general plan of the "Red Book". Dr. Pearn has earned the gratitude of that large body of excellent men and women who, although at times subject to criticism, spend their time in a very arduous but nevertheless fascinating vocation.

A Bibliography of Sex Rites and Customs: an Annotated Record of Books, Articles and Illustrations in all Languages. By Roger Goodland. Pp. v + 752. (London: George Routledge and Sons, Ltd., 1931.) 63*s.* net.

MR. GOODLAND'S bibliography of sex rites and customs is a monumental work of 9000 entries, which have taken, we gather, between fifteen and twenty years to compile. The entries are arranged alphabetically under authors' names. The place of a subject-catalogue, which is essential in a work of this kind if it is to be of any practical use, is taken by a copious subject-index. In view of the present cost of printing, this is perhaps the best solution of a difficulty which confronts every bibliographer. Mr. Goodland, however, has added greatly to the value of his work by the inclusion under each entry of a brief indication of the precise subject or subjects with which the book or paper deals, giving the page reference for each topic. A high standard of accuracy is maintained, and a careful scrutiny of the entries has not revealed any serious omission or error. Such omissions as have been noted would seem to be due to Mr. Goodland's interpretation of what is to be regarded as ritual.

Oxygen and Everest.

By RAYMOND GREENE.

THE recent success of the British Himalayan Expedition in climbing, without the use of oxygen, ten of the greater Himalayan peaks, including Kamet (25,447 feet), the highest summit yet attained, has brought once more into prominence the question of the use of oxygen on Everest. It is a question on which both climbers and physiologists are divided. It is possible that an attempt to sum up the present position may be of use in future discussion.

The problem to be solved is whether or not oxygen can be regarded as a helpful factor in high climbing. One school of thought claims that, in the face of theoretical considerations and practical experience, it is impossible to deny its usefulness. The special difficulties of Everest are due chiefly not to terrain or climate but to want of oxygen. To supply this want can scarcely fail to reduce the difficulties of the ascent. Moreover, Prof. J. Barcroft has shown by direct experiment that, under laboratory conditions, it is possible to do by means of oxygen what is certainly impossible without it—to climb at a rate of a thousand feet an hour, without previous acclimatisation, at a barometric pressure equal to that of the summit of Everest. Much practical experience points in the same direction. Of the ascent of the Rapiu La (21,000 feet), Prof. G. I. Finch wrote: "Colonel Strutt and Doctor Wakefield, unoxygenated, accompanied us on this little expedition, and oxygen at once proved its value, so easily did Bruce and I outpace them". Later, writing of May 22, 1922, he recorded that "There had been a considerable amount of step-cutting, but even so, oxygen had made a brief alpine ascent of what is otherwise a strenuous day's work". Of May 24 he wrote: "No longer did the porters regard oxygen as a foolish man's whim. One and all appreciated the advantages of what they naïvely chose to call 'English air'." As to its use in emergency, I will again quote Finch. He and Geoffrey Bruce had spent a miserable night at a height of 25,500 feet, about the height of Kamet. The weather was cold and windy but they decided to spend a second night at this camp. He wrote: "a dead, numbing cold was creeping up my limbs, a thing I had only once before felt. . . . Something had to be done. Like an inspiration came the thought of trying the effect of oxygen. . . . A few minutes later, after the first deep breath, I felt the tingling sensation of returning life and warmth to my limbs. We connected up the apparatus in such a way that we could breathe a small quantity of oxygen throughout the night. The result was marvellous. We slept well and warmly. Whenever the tube delivering the gas fell out of Bruce's mouth as he slept, I could see him stir uneasily in the uric, greenish light of the moon as it filtered through the canvas. Then, half unconsciously replacing the tube, he would fall once more into a peaceful slumber. There is little doubt that it was the use of oxygen which saved our lives during this second night in our high camp." On the next day, the two climbers climbed a further 1800 feet at an average speed of nine hundred feet an hour. An earlier party, using no oxygen, a stronger party from a mountaineering point of view, in better weather and after only one night in the high camp, covered roughly the same zone of altitude at a speed of only 330 feet an hour. It is on such data, derived from theoretical considerations, laboratory experiment, and practical experience, that the oxygen school bases its conclusions.

The no-oxygen school claims, on the other hand, that the conclusions are unsound because, both in the Barcroft steel chamber experiment and on Everest, the 'subjects' were either unacclimatised or only partially acclimatised. Acclimatisation appears to occur in three different ways. In the well-trained person, oxygen secretion by the lung epithelium increases the oxygen supply to the blood at a very early stage of an ascent. The existence of oxygen secretion is denied by some physiologists. In this battle of the giants I do not propose to take a part. It does not affect our main issue, because it does not occur to a sufficient extent to affect the question of whether or not oxygen should be carried on Everest. A great increase in the hæmoglobin percentage of the blood undoubtedly occurs, but this increase will not make possible the continuance of life at very great altitudes, unless supported by an actual increase in the pressure of oxygen in the lung alveoli. This increase is attained by deep breathing.

The first deep breathing of the ascending climber is caused by the effect of oxygen want, which increases the susceptibility of the respiratory centre to an increase in the carbon dioxide of the blood. The 'subject' responds to oxygen want by breathing more deeply. In so doing he washes carbon dioxide out of his blood and so lowers the acidity of the latter, and the tendency towards deep breathing. He may even show the periodic type of breathing known as 'Cheyne-Stokes breathing'. The most important element of acclimatisation is the overcoming of this 'alkalosis', and the breaking of the vicious circle. This compensation is brought about by an increased excretion of alkali by the kidneys. Thus a compensation towards acidosis is produced and permanent deep breathing with increased oxygen tension follows. Now the exponents of oxygen point out that although it is obvious that the supply of oxygen to an unacclimatised person would increase his working capacity, the acclimatised person would be unaffected. His deep breathing keeps his oxygen tension as high as he wants it.

The no-oxygen school can also quote from practical experience, for the evidence of the 1924 Everest Expedition was less favourable than that of the 1922 Expedition. There is, it is true, a record of a quick oxygen-assisted climb between Camps III. and IV. by Mallory and Irvine, and there is a note by Mallory, written from Camp VI., telling Noel to be on the look-out with his cinema at 8 A.M., when he expected to be at the foot of the final pyramid. This suggests that Mallory expected to make, with oxygen, very rapid progress. On the other hand, Geoffrey Bruce and Odell both reported that they obtained little or no benefit from its use. The first such occasion was up to 23,000 feet, where its use could scarcely be expected to produce dramatic results in acclimatised climbers. The second occasion was at 27,000 feet, when Odell discarded oxygen and felt better without it. With the deference due from one who was not actually present, I suggest that the fault may have rested with the apparatus, and that the improvement in Odell's condition may have been due to the discarding of useless weight and partly possibly to the euphoria usually associated with anoxæmia. We know that the apparatus was cumbersome, inefficient, and leaky. We do not know to what extent Irvine's improvements and corrections, carried out without proper equipment and under the most difficult of conditions, may have broken down in use. The appearance of Mallory and Irvine, still below the final pyramid at 12.50, four and a half hours late, may have been due to a breakdown of the apparatus.

If, then, the oxygen school believes in the usefulness of oxygen for high climbers, whether acclimatised or not, and the no-oxygen school believes in its usefulness for the unacclimatised, a method of attack in conformity with both points of view appears at first sight to be obvious. It should be possible to eliminate the necessity for acclimatisation by using oxygen from a low level on the mountain and climbing it at alpine speed. But here two great problems present themselves. It is very difficult to construct an apparatus which will without waste deliver the required quantity of oxygen while the climber is eating and sleeping; and it is impossible at the moment to find an apparatus which can be trusted never to go wrong. The failure of his oxygen apparatus near the top of Everest would mean death to the unacclimatised mountaineer.

The other extreme view has also been presented, but never by anyone with experience of Himalayan climbing—the view that Everest should be attacked by a party prepared, if necessary, to spend a year upon the mountain. To rush a mountain is folly, unsound in theory and disastrous in practice. Siege tactics have been proved sound. But there must be moderation even in slowness. The weather of the great peaks allows only a limited time in which to make the ascent, and many months upon a mountain undermine the health of the climbing party. It is possible that before sufficient acclimatisation for an oxygenless assault on the summit of Everest has been attained, altitude deterioration may have set in. If by relying on oxygen for the last few thousand feet of Everest it is possible to reduce the time on the mountain and thus the danger of deterioration, the chances of a successful attempt will be increased. Whether this can be done will be determined by direct experiment in a steel decompression chamber.

The practical difficulties of oxygen are serious. The apparatus in use in 1924 was so heavy that, in the opinion of some, its weight outbalanced its advantages. Valves tend to freeze or leak, and complicated taps are difficult to work under trying conditions. Many improvements have been made in the last five years, but there is room for more. There should be produced a light, simple, and efficient apparatus, thoroughly tested in refrigerators and mid-tunnels and on the mountains of Europe. This task has been undertaken by a committee of the British Association. If such an apparatus can be designed it should, as soon as permission can be obtained, be placed in the hands of a young, well-drilled, and well-organised party. Such a party will, in my opinion, climb Everest. It will at any rate show us whether or not oxygen can be of service to the unacclimatised man.

The Principles of Evolution Revealed by Palæontology.*

By Prof. Henry Fairfield Osborn, For.Mem.R.S.

In honour of Darwin our first thought is that natural selection is the sole survivor of the age-long theories and hypotheses clustering about evolution. Selection alone has stood the test of survival of the fittest, yet we must severely limit the powers of selection as Darwin imagined them in his earlier and more sanguine frame of mind, and glean the elements of truth pervading all the other hypotheses and theories. It is a striking fact that the zoologists, experimentalists, and geneticists who, a quarter century ago, were stoutly combating Wallace, Weismann, and other super selectionists, have, one after another, returned to the Darwinian fold and are now almost unanimously teaching their students, as if it were a demonstrated fact, that evolution progresses by the survival of fortuitously adaptive mutations.

To the mind of the palæontologist these teachings are pure Darwinism camouflaged in new language. Bateson, founder of the genetic school, was the only one to confess frankly his utter failure to explain the origin of species; few have displayed similar courage.

When we consider the youthful zoology and the infantile palæontology of Darwin's time (1809–82), our admiration for his genius and marvellous powers of generalisation constantly increases. What would his generalisations have risen to with our present knowledge? He foresaw the promised land of palæontology, but did not live to enter it. The ratio of the 8767 vertebrate species known in his time to the 65,939 species known in 1925, nearly 8 to 1, is about the measure of the biological progress of the first century of evolution. The 'biochemical' adaptations underlying coloration, as well as the 'biophysical' adaptations controlling many of the animal instincts, are beyond the ken of the palæontologist who is bounded by his biomechanical fossils.

---

* Paper read before Section D (Zoology) of the British Association, following Prof. E. B. Poulton's presidential address, entitled "A Century of Evolution", on Sept. 24. This is the sixth of a series of papers by the author on the origin of species

Far from marking any real progress toward the eternal question of the origin of co-ordinated mechanical adaptations, the experimental zoologist and geneticist are making little progress along the biochemical line. In order to ascertain the state of current observation and opinion on the mutational origin of species, sub-species, or adaptive mutations, as well as on the experimental results of biochemical, biophysical, and endocrine action, the following questionnaire (slightly modified) was sent out on July 17, 1931, to forty-one leading zoologists:

1. Do you know of a single concrete case of the origin of a species, of a sub-species, of an adaptive mutation of De Vries, or of a single adaptive character, arising suddenly by mutation or saltation either under natural or experimental conditions?
2. Granted that permanent hereditary sports, mutations, and modifications of existing characters are being produced by biochemical and biophysical means, has a single adaptive character been produced by such means by experiment in your laboratories?
3. Granted that profound changes in colouring, in form, in somatic proportion, in the developmental acceleration or retardation of characters, may be produced by glandular action, is there sufficient evidence that Nature has ever proceeded in this way except in producing immunity and non-immunity?

Up to the present time (Aug. 13) seventeen replies have been received. To Questions 1 and 2 the prevailing answers are negative as indicated by the reply "No". More or less positive or affirmative replies were also received to Question 1, but analysis of most of these replies indicates that the crucial element in Question 1 is evaded, namely, *the origin of adaptive characters*. No doubt certain mutations do survive; many of them are recorded in the answers to the questionnaire; Crampton has discovered mutations in his monographic researches on the mollusc *Partula*; Chapman in the avian genus *Buarremon*; the short-legged Ancon sheep is a classic; certain biomechanical mutations in the pelagic Ciliata, such as the spiral shelf of *Xystonella scandens* observed by Kofoid, may be of sudden or mutational origin although this is not proved. The answers of seventeen zoologists to Question 2, namely, to adaptive biochemical origins by experiment, are uniformly negative; new and hereditarily permanent mutations may be aroused by more or less violent chemical or physical means, but not a single one is known to be adaptive. The answers to Question 3 are five negative and five affirmative; the negative squarely meeting the question, the positive reaffirming the granted postulate that endocrine secretions profoundly modify all existing characters and processes of development, but not a single case can be cited wherein a new biomechanical character has arisen through endocrine action.

In this struggle for existence of bygone theories and of new hypotheses, it seems that palæontology, with its world of new and wholly undreamt of evidence as to the *origin of adaptive biomechanical characters*, serves as the two-edged sword of biology; it cuts hypotheses unfit to survive; it strengthens hypotheses fit to survive. It calls for conceptions of a new and synthetic physicochemical order to supplant outworn hypotheses dating back to Empedocles (600 B.C.). Palæontology disestablishes the entelechy hypothesis of Aristotle (300 B.C.) and of all his 'vitalistic' followers like Driesch and Bergson. It substitutes for Aristotle's 'internal perfecting tendency' the idea of adaptive reaction and interaction of internal with external energies which has been formulated (Osborn, 1912–1929) into a new *tetraplastic* principle of the 'four inseparable energetic factors of evolution', namely: (1) physical environment, (2) ontogeny including habit, (3) living environment, the biota, (4) the germ plasm. The above energetic complex is subject to the non-energetic selection—survival of the fittest.

This tetraplastic principle which seeks to combine the elements of truth in preceding hypotheses and theories has, thus far, won no acceptance.

In causation of the origin of species and subspecies, palæontology unites with modern field zoology in firmly establishing the direct action of environment (Buffon, 1755–Wagner, 1870) on the germ plasm as a causative factor. It disestablishes the habit-inheritance law of Erasmus Darwin and of Lamarck (1790–1809); through auto-adaptation it establishes habit as a *guiding* principle in evolution, but not in the Lamarckian sense. Palæontology eliminates selection from the energetic complex; it establishes the non-energetic selection as a universal and outstanding guide and principle of progress from the beginning of time; it disestablishes the third and fourth principles of Charles Darwin (1859), namely, of the origin of adaptations through the survival of the fortuitously adaptive. It firmly establishes the inconspicuous adaptive origins of new characters first observed by Waagen (1869), which may be distinguished as *W.* mutations when compared with the fortuitous *D.* mutations of De Vries (1911). At least from biomechanical evolution it excludes entirely the fortuitous *D.* mutations of De Vries. It helps to disestablish the 'pangenesis' of Darwin and all similar theories of the somatic origin of adaptive characters; it accordingly disestablishes the 'inheritance of acquired characters' and establishes the complementary principle of the 'continuity of germ plasm' of Weismann (1880). It disestablishes the super-selection theories of Weismann and other neo-Darwinians. In its earliest (1806), as well as its latest phases (1931), palæontology undermines the primitive idea of 'created evolution'; of recent years it tends to establish the wholly different idea of 'creative evolution', which may be provisionally termed *aristogenesis*. Finally, palæontology unites with systematic and experimental zoology in compelling us to concentrate research on the origin and co-ordination of bio-characters, in the lower animals and in man, as the outstanding problem of the second century of evolution.

Although primarily an original observer rather than a collator of other people's ideas, Darwin was more or less familiar with ten of the principles of ' biomechanical ' adaptation which had been observed in the hard parts of animals from the time of the earliest Greek anatomists and philosophers. Throughout his frequent discussions of the biomechanical evolution of animals, are included the bony and muscular adaptations brought about through processes of (1) degeneration, (2) development, (3) compensation, (4) economy, (5) change of proportion, (6) co-adaptation, (7 and 8) acceleration or retardation, (9) self-adaptation, and (10) sports and discontinuities. One great principle remained to be established after his time, namely, (11) continuity of the germ plasm, in antithesis to all pangenetic hypotheses of the origin of hereditary characters. Note that all these ten pre-Darwin principles of adaptation relate not to the *origins of organs*, but to the *modification of existing organs*, as of the wings of the duck, the neck of the giraffe, the speed of the wolf. Darwin realised that the weak point in his theory was in the matter of origins ; he could, and did, largely explain the survival value of organs once established, but was hard put to place a survival value on fortuitous variations.

Palæontology (1869–1931) has changed all this through a succession of discoveries revealing nine principles of *adaptive biomechanical origin in the germ plasm*. Thus, up to the present time, we have established through zoology and palæontology no less than twenty more or less distinct but invariably co-operative principles of bio-mechanical adaptation, as follows :

Modification of Existing Organs, Ontogeny.

Discovered in Anatomy and Embryology.
Known to Darwin.

1. Biomechanical *onto-retrogression* (Aristotle), degeneration, atrophy of organs.
2. ,, ,, *-progression* (Aristotle), development, hypertrophy of organs.
3. ,, ,, *-compensation* (Aristotle), metatrophy and eutrophy of organs.
4. ,, ,, *-economy* (Aristotle), metatrophy and eutrophy of organs.
5. ,, ,, *-allometry* (Lamarck-Darwin), allometrons, changes of proportion in organs.
6. ,, *co-adaptation* (St. Hilaire), co-ordination, correlation of organs.
7. ,, *onto-acceleration* (v. Baer) into earlier growth stages of organs.
8. ,, ,, *-retardation* (v. Baer) into later growth stages of organs.
9. ,, *auto-adaptation* (Goethe) through principles 1-8.
10. ,, *onto-saltation* (St. Hilaire), sports, discontinuities.
11. ,, ,, *-continuity of germ plasm in the perpetuation of organs* (Weismann).

Origin of New Characters, Phylogeny.

Discovered in Palæontology.
Not known to Darwin.

12. Biomechanical *phylo-mutation* (Waagen, 1869), orthogenesis in new characters.
13. ,, *-trend* ' mutations-richtung ' (Neumayr) in new characters.
14. ,, *-acceleration* (Hyatt, 1880) in the evolution of characters.
15. ,, *-retardation* (Hyatt, 1880) in the evolution of characters.
16. ,, *-continuity* (Osborn, 1889–1931) vs. discontinuity in characters.
17. ,, *-potentiality* (Osborn, 1889–1931) in the origin of new characters.
18. ,, *-predetermination* (Osborn, 1889–1931) in the origin of new characters.
19. ,, *-rectigradation* (Osborn, 1889–1931) in the origin of single characters.
20. ,, *-aristogenesis* (Osborn, 1889–1931) in the rise of characters.

Of the nine principles of biomechanical origin discovered in phylogeny since Darwin's " Origin of Species " (1859), the first three were observed in fossil invertebrates, namely : (12) the *D.* mutations of Waagen (1869), in which is involved (13) the ' trend ' or ' mutations richtung ' of Neumayr (1875); (14-15) the ' acceleration and retardation ' of Hyatt (1880), principles which Darwin could not clearly comprehend. In the year 1889, Osborn, at the time a convinced neo-Lamarckian, began his extremely intensive observations upon the origin and development of single adaptive characters, aided by unprecedented fossil material first in the primates and then in five independent divisions of the ungulates, wherein were revealed five previously undiscovered principles of biomechanical adaptation, namely : (16) germinal continuity versus discontinuity, and *W.* mutations ascending and descending ; (17) germinal potentiality, as a basis of Lankester's principle of *homogeny* ; (18) germinal predetermination, as distinguished from indeterminate origins ; (19) germinal rectigradations, as distinguished from fortuitous or chance origins. Finally, in the synthesis of the orthogenetic origin of new adaptive characters in all the mammals, including man, there was reached (20) the principle now provisionally termed *aristogenesis* for the want of a more appropriate word to express continuously creative adaptation.

A very important distinction is observed between *rectigradations* which are predetermined, and changes in proportion, as in the elongation of the neck of the giraffe, technically known as *allometrons*, which are not predetermined. Rectigradations are relatively rare, while allometrons, or changes of proportion in the teeth, skull, and limbs, are constantly in progress and make up a larger part of the definition of species. Similar rectigradations arise through community of descent. Similar allometrons are constantly arising in animals of dissimilar ascent.

Whereas the zoologist, comparative anatomist, and geneticist by the very nature of the evidence at their command, find difficulty in distinguishing between the accidental, fortuitous, and temporary variations, fluctuations, and *D.* mutations, the palæontologist is absolutely sure of his footing as soon as he is enabled to observe the ascending geological mutations of animal mechanisms, whether invertebrate or vertebrate. He advances solely by inductive means, after the manner of Darwin. If he is not sure of the adaptive trend of a certain rectigradation in its feeble, incipient stage, he may observe it a hundred thousand or a million years later as the dominant and commanding character of the entire organism. As Weismann spoke of the immortality of the germ plasm, the palæontologist may speak of the secular immortality of thousands of characters which he is enabled to observe through the whole cycle from potentiality and predetermination in the germ plasm until, after æons of use and service, they may subside again into the mysterious germinal substance—mysterious because utterly inexplicable. The biomechanism of the titanothere and of the elephant is due to a complex of energetic factors which is entirely beyond our present comprehension.

The palæontologist concludes that the origin of species, so far as species are defined by various stages of biomechanical adaptation, has long ceased to be a problem; the manner by which sub-species, species, genera, families, and orders arise through divergence, acceleration, retardation, and rectigradation is also perfectly clear.

Selection acts incessantly, but it originates nothing, and it does not control either the origin of characters or their rate of evolution after they arise.

We can affirm that it is the essential living principle of biomechanical reaction which calls forth the adaptive biomechanical response, whether in ontogeny or in phylogeny.

While we know infinitely more about the principles of evolution than did Charles Darwin, and while we can demonstrate beyond refutation the prevailing twenty principles of biomechanical adaptation discovered in ontogeny and phylogeny, *we are more at a loss than ever before to understand the causes of evolution.* One after another the Buffonian, Lamarckian, Darwinian, Weismannian, and De Vriesian theories of causation have collapsed; each, however, contains elements of truth. All that we can say at present is that Nature does not waste time or effort with chance or fortuity or experiment, but that she proceeds directly and creatively to her marvellous adaptive ends of biomechanism.

Biology and Civilisation.

IN his Norman Lockyer lecture, delivered to the British Science Guild on Nov. 24, Dr. H. H. Dale dealt with the part which biology and biologists should play in modern civilisation. It is a commonplace that physical science and mechanical inventions have probably made greater changes in the conditions under which human beings live in the past hundred and fifty years than in the preceding twenty centuries. But this progress has led to many thinking of it in quantitative rather than qualitative terms, and forgetting that machinery was made for man and not man for machinery. It is possible that the imposing achievements of physical science have already, in the thoughts and interests of men at large, in our educational and public policy, as well as in technical and industrial development, overshadowed those of biology to an extent which threatens a one-sided development of science itself, and of the civilisation which we hope to see based on science.

Dr. Dale illustrated his argument by a reference to the physiological problems involved in flying. At the beginning of the War, physiologists were consulted on the subject of the difficulty of breathing at high altitudes. They sought permission to take small quantities of blood for investigation, and were asked by the authorities, what had blood to do with breathing? The question was not easy to answer with polite brevity, since British physiologists had, for several hundred years, been attempting to describe what blood has to do with breathing, and how it does it. To-day physiology has a proper place in the research organisation of the Royal Air Force; and with the development of machines capable of flying at several hundred miles an hour, has come the realisation that the reactions of the human organism to the stresses occasioned by these great speeds will play an important part in any further advances and may well prove to be the limiting factor.

Although biology and physical science have supplemented each other in our modern civilisation in such directions as the provision of pure water supplies and the disposal of sewage, in other directions there has been a lamentable divergence. The pollution of the atmosphere by smoke involves not only a direct waste of fuel and destruction of other materials, but also a very definite increase in ill-health from the absence of direct sunshine, which may be indicated indirectly by the stifled and stunted plant life in our northern cities and directly by the presence of rickets—the 'English disease' of German medical writings—among the growing children.

Dr. Dale described in some detail how our present knowledge of the etiology of this disease has come about. It is now certain that it is due to the absence from the body of a compound which is known as vitamin D, which can be supplied either in the food or by exposure of the surface of the body to the sun's rays, or to some artificial source of light. The vitamin is formed from a compound known as ergosterol, under the action of the rays in the shorter wave-length region of the solar spectrum, either in the skin or in any food material containing its precursor. In practice, for its manufacture, an artificial source of light is used, which emits more of the shorter wave-lengths than reach the earth's surface from the sun. Recent work by Bourdillon and his colleagues in Great Britain, and by Windaus in Germany, has led to the preparation of a pure crystalline compound, of very great activity, which is probably the vitamin itself. In spite of our knowledge of the necessity of supplying vitamins to growing children, margarine still too frequently replaces butter in their diet. Surely a community which respects human life should insist on the production of margarines biologically equivalent to, as well as physically like, butter.

Looking further afield and considering the problem of the qualitative and quantitative dietary needs of men of different races of civilisation, in all varieties of climate, it appears that only the fringe of this great problem of human nutrition has begun to be touched by science. It is very probable that a large proportion of the human race is living at a nutritional level which prevents them from achieving more than a small part of the physical and mental efficiency of which they are racially capable.

Even the bodily well-being of man demands more than food. We have not properly begun to use the available resources of physical science to provide for other factors of a healthy environment, nor have we properly applied the botanical and zoological knowledge which bears on the problems of disease, or made the fullest efforts to extend it. In cold or temperate climates, the white races can only exist in winter with the aid of artificial heat; in the tropics no attempt has so far been made to supply artificially cooled houses. Again, we are only beginning to realise the dimensions of such problems as those presented by the tsetse flies, by the plagues of locusts, and by the hosts of external and internal parasites which prey upon the higher animals and plants.

Dr. Dale referred to the recent work on virus diseases, pointing out that it is probable that biological research has here reached a point at which progress is delayed, because it is trying to advance beyond the range of the methods which physical science has yet made available. There are other points at which functional biology finds itself halting for want of physical methods of the required delicacy and precision. The work requires a partnership between biology and physics, of which there is little sign at present. The lack of it is connected with the tendency, referred to above, to a one-sided development of civilisation.

The causes of this are complex. They are partly due to the increasing specialisation which accompanies increased knowledge, partly to the fact that biology, in its observational and systematic stage, was considered to demand a smaller intellectual effort than the sciences of chemistry and physics. To-day, biology calls to its aid the resources provided by the latter sciences, as seen, for example, in the work carried out on the processes accompanying a simple muscular contraction. It is making a bold approach to the task of analysing vital processes into sequences of associated chemical reactions. The problems differ from those with which the ordinary chemist deals only in their complexity and difficulty. The reactions proceed with extraordinary rapidity, and the substances concerned are very unstable and are present in only minute amounts. Organic chemistry, which started as the chemistry of living organisms, has been prone to forsake its original objective for the fascinating pursuit of making unnatural substances by artificial synthesis, for practical use in industry or medicine, or for their theoretical interest. Similar complexities face the physicist who may interest himself in biological problems; in fact, although the cleavage between the physical and chemical sciences and biology may have been inevitable when the problems of biology seemed too superficial and too easy, it is of the utmost importance to the future that this cleavage should not persist unnaturally, because the problems of biology are now becoming too complex and too difficult.

The widespread desire to know something of the achievements of science is concerned almost solely with those of physical or chemical science, and the unequal concentration of this interest, reflected in our educational and administrative systems, may become a real danger to our civilisation. An intelligent appreciation of the fundamental facts of biology is not regarded as a necessary part of the equipment of an educated man. Even an eminent physicist may preserve his aloofness from biological knowledge to a degree quite impossible to the normally educated biologist in relation to physics and chemistry. This anomaly in our education is part of a vicious circle: it arises in response to a one-sided demand of our civilisation, which, in turn, it tends to confirm in its asymmetry.

The problem of the improvement of the human race is ultimately biological and demands a biological outlook for its investigation. Thus it involves the application of genetics to the production without conflict with the existing social order of desirable human types. The problem is difficult, but this does not justify us in ignoring it; on the contrary, it makes more urgent the need for the most complete scientific knowledge that can be obtained. Such biological knowledge may make the human race capable of a civilisation beyond any that we can imagine at the present day.

Obituary.

DR. JOHN SAMPSON.

BY the death on Nov. 8 of John Sampson, D.Litt., for many years librarian of the University of Liverpool, England loses its most eminent Gypsy scholar. He became interested in Gypsies, more particularly on the linguistic side, as a young man; and after exhausting the possibilities of English Romani, which indeed is a poor, broken-down dialect, he turned to the fully inflected speech of the Welsh Gypsies descended from Abram Wood. That was in 1894, prior to which its existence had barely been proved. Thirty-two years later, there appeared from the Oxford University Press his massive, scholarly, and, for a philological work, intensely human, "Dialect of the Gypsies of Wales", the 660 closely printed quarto pages of which provide, not only the best account yet published of any Romani dialect, but also, despite a few omissions imposed by the nature of his subject, the fullest and most accurate exposition available of the phonetics and morphology of the Gypsy language as a whole.

This imposing book, and the series of Welsh Gypsy folk-tales Dr. Sampson published in the *Journal of the Gypsy Lore Society* at intervals during the past twenty-five years, may be regarded as his life work. But he also contributed numerous other papers to the pages of that journal. One of them, read before the British Association in 1923, is a very original and largely successful attempt, based mainly on phonological data, to trace the migrations of the Gypsies on Asiatic soil prior to the date of their first appearance in Europe. In another, written more than forty years ago, he solved the riddle presented by Shelta, the jargon of the Irish tinkers often met with on the English roads; an ancient jargon, invented, as his friend Prof. Kuno Meyer proceeded to show, by the Irish bards.

WE regret to record the death of the Rev. F. Smith, formerly a chaplain in the Royal Navy, which took place at Nottingham, where he had lived since his retirement in 1917. Mr. Smith was best known to archæologists for his advocacy of the existence of early man in Scotland during the interglacial periods of the Ice Age. With the late Dr. Gemmell, of Drummers, Wigtownshire, he had made a large collection of specimens, some of enormous size and of rocks other than flint, which he held showed evidence of man's handiwork and supported his contention. His conclusions and a summary of the evidence on which they were based were embodied in his "The Stone Ages in North Britain and Ireland", published in 1909. A close student of the technique of stone implements, he maintained that the readiness with which the hand adapted itself to the grip of a doubtful artefact was a sure test of genuineness—a view he applied in his "Prehistoric Man and the Cambridge Gravels", published in 1926, in dealing with specimens of which the human origin had not generally been accepted. This winter a part of the collection made by Mr. Smith and Dr. Gemmell is being exhibited in Glasgow.

News and Views.

THE weekly meeting of the Linnean Society held on Nov. 19 was devoted to a series of papers commemorative of Robert Brown, the eminent nineteenth century botanist. In November 1831 he announced to the Linnean Society his discovery of the nucleus of the vegetable cell. The authors of the papers presented were: Prof. F. E. Weiss (president), Mr. J. Ramsbottom, Mr. S. Savage, and Lieut.-Col. J. Stephenson. A number of interesting original documents and prints illustrative of Brown's career were on view. Also, a portrait and a bust of the botanist belonging to the Society were placed, for the occasion, close to the presidential chair. Robert Brown was the son of an Episcopalian minister, and was born at Montrose, on Dec. 21, 1773. Educated there at the Grammar School, he proceeded in 1787 to Marischal College, Aberdeen, entering afterwards the medical faculty of the University of Edinburgh. He was strongly interested in the studies of the pioneer botanists of his time. Visiting London in 1798, he met Sir Joseph Banks, and henceforth botanical research work and allied interests dominated his energies. The recommendation of Banks, in 1801, secured his appointment as naturalist to H.M.S. *Investigator*, commissioned under Capt. Matthew Flinders to conduct a survey of the coasts of Australia. After nearly four years' absence, Brown returned with a collection of some four thousand species of plants, mostly new to science. He did not, however, overlook the demands of zoology.

IN 1805 Brown was appointed librarian to the Linnean Society, thereafter devoting himself in his hours of leisure to the working out of his collections, contributing largely thereby to perfecting the natural method of classification. In 1810 he published the first instalment of his famous "Prodromus Floræ Novæ Hollandiæ". He assisted also in the accounts of various scientific expeditions; for example: Salt's "Travels in Abyssinia", Clapperton's "Expedition to Central Africa", and Strutt's "Expedition to Central Australia". In 1810 Brown became librarian to Sir Joseph Banks and keeper of the collections at his house in Soho Square; afterwards (1827), when the collections were transferred to the British Museum, Brown followed thither in charge of the botanical sections. Brown was president of the Linnean Society from 1849 until 1853. Residing in Banks's old home in Soho, he died there on June 10, 1858, at the age of eighty-five years. At the meeting of the British Association at Oxford in 1832, honorary degrees were conferred by Convocation on Robert Brown, Sir David Brewster, John Dalton, and Michael Faraday. In Brown's case the distinction was that of D.C.L. It was this little group which prompted Keble's allusion to a "hodge-podge of philosophers" as being present in the city. Elected a fellow of the Royal Society in 1811 (Banks, as president, was, likely enough, chief sponsor), Brown was awarded the Copley Medal in 1839 for his discoveries on vegetable impregnation.

ON Dec. 5 occurs the centenary of the birth of Hans Heinrich Landolt, the eminent Swiss chemist whose work formed a connecting link with that of Mitscherlich, Rose, and Bunsen, and who counted among his contemporaries and friends Lothar Meyer, Beilstein, Kekulé, and Quincke. Born at Zurich, he was a descendant of an old patrician family of Switzerland. He entered the University of Zurich and wrote his first paper at the age of nineteen years, and his labours as a chemist did not cease until a week before his death, which occurred on Mar. 15, 1910, when he was in his seventy-ninth year. Leaving Zurich at the age of twenty-two, he studied at Breslau, and thence entered the laboratory of Bunsen at Heidelberg. For twelve years, 1857–69, he was associated with Hofmann and Kekulé at Bonn, and in 1869 he was made head of a new technical institute at Aix-la-Chapelle. From 1880 until 1891 he directed the newly founded Agricultural College at Berlin and was next appointed to succeed Rammelsburg in the University of Berlin. At Heidelberg, Landolt carried out researches on the electrolytic production of calcium and lithium, and on the gases produced in the newly invented Bunsen burner. At Bonn he studied the influence of the atomic composition of liquids on the transmission of light, at Aix-la-Chapelle he carried out his important work on polarised light, while at Berlin he turned his attention to the determination of melting points, the crystalline structure of substances, and, between 1893 and 1908, carried out his well-known series of experiments on the conservation of mass during chemical reactions. A man of placid disposition, Landolt possessed infinite patience, and in his old age was regarded as a patriarch of physical chemistry. His death took place at Berlin, but he was buried at Bonn, where he had spent some of the happiest years of his life.

SIR CHARLES PEERS, in his address to the annual Congress of Archæological Societies, which was held in the rooms of the Society of Antiquaries on Nov. 17, directed attention to the first session of the Congrès International des Sciences Préhistoriques et Protohistoriques to be held in London in August 1932. He reviewed briefly the circumstances leading up to the decision, taken by representatives of a number of countries meeting at Berne in May last, to found a new Congress after the failure of protracted negotiations for placing the Congress organised by the Institut International of Paris on an international basis. Sir Charles also pointed out that the old International Congress of Prehistoric Anthropology and Archæology, which first met at Spezia in 1865 and held its last session at Geneva in 1912, met in London in 1868, but no congress of prehistoric studies has been held there since that date. The invitation to hold the Congress in London tendered by the Society of Antiquaries and the Royal Anthropological Institute, acting in conjunction with its Joint Committee for Research and Teaching, has received the support of the Royal Archæological Institute and a number of other bodies engaged in cognate studies. The need for an international gathering of this character at regular intervals—the congress will meet normally once every four years—has been felt with increasing urgency for some time; and this movement towards international co-operation in prehistoric studies, therefore, merits the strongest support among the many circles of widely varied interests with which the local archæological societies are in touch. The range of subjects —geology, palæontology of plants and animals, anthropology, ethnography, folk-lore, and archæology—ensures ample material to occupy a membership of the most diverse character.

ON several occasions the local archæological societies of Great Britain have been invited, through their annual congress, to co-operate in the collection and study of material which, either because it is too widely extended geographically or because it requires local knowledge, is beyond the range of the individual. The work of the Committee on Earthworks is a case in point. At the last Congress, Mr. H. J. E. Peake appealed on behalf of the British National Committee on Folk-Arts and Crafts for information relating to arts and crafts still practised among the people in the countryside, while Dr. G. Herbert Fowler asked the societies to promote a survey of parish documents. Both these matters unquestionably require the attention of local societies, although in the case of parish documents it was pointed out with justice that some county councils already have done much to arouse local interest in these records and thus to ensure their preservation. The urgency of Mr Peake's request must be measured by the fact that it comes almost too late. Although a number of folk-arts and crafts are still practised even now, and some, owing to local circumstances or their special adaptability to local needs, are quite likely to survive for some time, yet the last few years have witnessed rapid strides towards the extinction of many traditional industries and methods. When an attempt was made to institute an ethnographic survey of the British Isles without success some thirty years ago or more, an opportunity was lost which cannot recur.

INDIGNATION is being freely expressed in Australia at the action of the Commonwealth Government in imposing a primage duty of 10 per cent on books imported from abroad, and a further sales-tax of 6 per cent. Almost all importation is from Great Britain, and, apart altogether from direct taxation, the purchaser suffers from an adverse exchange rate of 30 per cent in converting Australian currency into sterling. To educational institutions and scientific societies, and also, of course, to individuals (particularly students), these imposts are a very serious matter indeed. Federal labour ministers have so far shown scant sympathy towards the representations made by universities and other bodies. They plead that the need for revenue outweighs considerations of the burden upon scholarship and knowledge in general, a view which is deplorably short-sighted in any community, but especially so in a country so dependent upon outside sources for its literature as Australia is. Nor is the revenue contention finding justification in experience. In 1929 imports of books and other reading matter from Great Britain and Northern Ireland totalled well over one million pounds in value. For 1931 the indications are that the figure will not reach half a million. The taxes are defeating their own purpose by destroying the source of revenue; but, apart altogether from that side of the matter, they impose a serious handicap upon literary and scientific development.

THE Friday evening discourse at the Royal Institution on Nov. 20 was delivered by Dr. C. H. Lander, who took as his subject, "Oil and Petrol from Coal". In Great Britain, where there are no appreciable deposits of natural oil, but where coal is plentiful, the possibility of manufacturing oil and petrol from coal has obvious attractions. Liquid fuels were first made commercially from coal as a by-product in the manufacture of gas or coke. The total yield of motor spirit by such processes, however, cannot be pushed beyond some six or seven gallons per ton of coal carbonised. Coal, as compared with oil, is deficient in hydrogen; the problem therefore suggests itself of adding extra hydrogen to the coal substance in order to make up this deficiency, and then, by some means or other, inducing the molecules of the mixture to reshuffle themselves into oil molecules. Some fifteen years ago, Dr. Bergius, in Germany, succeeded in liquefying coal by direct hydrogenation.

SOON after the War, experimental work on the hydrogenation of coal was taken up at the Fuel Research Station, Greenwich, and at a later stage close collaboration was established with the German group. By 1927, Imperial Chemical Industries, Ltd., thought it worth while to explore the possibilities of its commercial exploitation, and a plant capable of dealing with about fifteen tons of coal a day is now in action at its Billingham Works and is producing some 160 gallons of motor spirit from the treatment of a ton of suitable coal. Extra coal is required for hydrogen manufacture and power generation, but, taking all the costs into account, the cost of petrol from the works is of the order of only *7d.* or *8d.* a gallon. The complete gasification of coal to hydrogen and carbon monoxide, and the subsequent synthesis of these gases for the production of alcohol and hydrocarbons, was also briefly referred to. Although such processes cannot at present compete with carbonisation or hydrogenation for the manufacture of liquid fuel, they have already become the basis of a large industry for the production of alcohol for solvents.

SPAIN will be the host of chemists from all parts of the world in April 1932, when the ninth International Congress of Pure and Applied Chemistry meets in Madrid. The occasion is one of distinction, for the Congress is the first to be held since the War, and the first to be held under the auspices of the International Union for Chemistry. The seventh Congress of Applied Chemistry was held in London in 1909, and the eighth in Washington and New York in 1912; the ninth congress at Madrid will also be associated with the eleventh Conference of the International Union of Chemistry. While the latter is a delegate conference, the Congress itself offers membership to anyone professing interest in any of its objects, namely, the advancement of chemistry and its applications, and the strengthening of relations between chemists of every nation. Additional importance is lent to the occasion by its official character, the assembly having been placed under the patronage of the Government of the Spanish Republic.

THE three subjects which have been chosen for discussion at the International Congress of Pure and Applied Chemistry are: the Raman effect in connexion with chemical constitution; the high polymers in chemistry; and the chemistry of high temperatures. Invitations to take part in the discussions have been extended to the following: Sir C. V. Raman (Calcutta), Prof. K. W. F. Kohlrausch (Graz), Prof. J. Cabannes (Montpellier), Prof. K. H. Meyer (Ludwigshafen), Prof. A. Staudinger (Freiburg), Prof. W. L. Bragg (Manchester), Prof. C. Matignon (Paris), Prof. O. Ruff (Breslau), Prof. A. Day (Washington). The proceedings will commence with a reception on April 3, and will terminate on April 9, although April 10 is reserved for trips; the principal discussions will take place on April 4, 6, and 8, whilst excursions and other social functions will be held on other days in that week. Meetings of the International Union for Chemistry will be held on April 8 and 9. Incidentally, the congress week will coincide with the holding of interesting festivals and fairs. Applications for membership of the Congress must be sent to the general secretary, Prof. E. Moles, San Bernardo 49, Madrid (8), before Jan. 1, 1932.

PRAGMATISM was the keynote of Mr. Olaf Bloch's presidential address, "The Faith of a Technical Man", delivered to the Royal Photographic Society on Oct. 20. The man of science believes in a real world, and to mix metaphysics and experimental science is fatal. The realisation of his comparative ignorance is characteristic of the modern man of science, and produces a mental attitude which, coupled with logic, imagination, and intuition, is largely responsible for our rapid technical progress. It is important to develop the attitude of fearless inquiry, of freedom from conventional shackles, which enables us to look at facts and problems from the outside. In this educational problem the man of science must play his part. Our political and social organisation has only permitted a tithe of the influence which scientific and technical advances have exercised in industry. The numerous factors involved should not deter the technician from attempting to deal with politics, economics, and public affairs in the abstract and logical way he applies in his own work. Production is already passing rapidly under his control, followed by distribution. In various directions, scientific methods have already been applied to human affairs to some extent, and the successful use of such methods in this field calls for great qualities, and in particular requires an internationalism which does not yet exist. Science, both pure and applied, is a great destroyer of barriers, and the international economic agreements already in force may be the beginnings of far-reaching developments.

MR. BLOCH stated that whether or not human nature can be changed, its outlook can certainly be modified by education, public opinion, or by the application of technical achievements to life so that human nature would have all the appearance of having been changed. Thus the technical advances which have so completely transformed and mechanised the production and even the distribution aspects of industry and agriculture are producing a type of mind which reacts more quickly, is less insular, and more open and willing to face problems in the light of facts rather than of tradition. Fundamentally, technical progress is only justified when accompanied by social, economic, and political progress—amelioration and increased amenities of life, greater security and more widespread education, knowledge, recreation, etc. At present, the coexistence of a highly organised and increasingly complex productive system with an inert and more or less antiquated social and political system tends to great instability, which can only be removed as we extend our organising powers from production, distribution, and consumption to the social and legislative problems at present so largely unco-ordinated. A wise administration would deliberately and unostentatiously plan to construct a true educational ladder, building up a higher average brain capacity. Race quality cannot be improved by statesmanship alone; the technical man must bring his scientific methods, insist upon their increasing application to the material concerns of life, and manifest his profound faith in the power of mind to compose, arrange, create, and cope with the difficulties and complexities of human affairs.

SIR ARNOLD WILSON contributed an interesting paper on "The Epic and the Tragedies of Civilisation" to the recent Modern Churchmen's Conference, and it has now been reprinted by Basil Blackwell, of Oxford, as a pamphlet. He quotes and criticises Spengler and Houston Chamberlain with good effect, and adds some wise warnings as to the durability and strengthening of civilisation, both in the past and the present, which historians and social reformers would do well to take to heart. Of the former, the most valuable is that we are coming to see that the pervading rule is that the old does not disappear in a cataclysm, as one is apt to think when reviewing the whole process after its completion. The barbarians, for example, did not sweep away the Roman Empire, but partly absorbed it and partly were absorbed. The change is mutual and continuous rather than catastrophic. With regard to the present and the future, Sir Arnold rightly dwells on the supreme importance of the use of leisure, on which, as he says, with the growth of wealth, "mainly depends the maintenance of a civilisation". Following on this he has a weighty passage, suggested by Mr. H. W. Nevinson, on the fundamental importance of the skilled manual worker as the creator of civilisation. It is a view which fits in well with the gospel which Dr. Jacks is never tired of preaching—of salvation by 'making'.

ONE grave omission, however, cannot fail to strike the reader of the brochure, an omission which it shares in common with most of the criticisms and prophecies of the delay of civilisations. Sir Arnold Wilson does not see, or at least does not mention, the transformation effected in the world by the scientific organisation of society in modern times. Wherever science, both as a method of thought and as an agent of mechanical adjustments, is established, society acquires a stability and a power of resistance quite unknown in earlier times. Lord Balfour pointed this out years ago in his presidential address to the British Association, but the literary historian goes on talking as if nothing of the sort had happened. Yet the War, which came after Balfour's address, gave the most striking confirmation. Scientifically organised communities, of which Germany was the leading example, have survived, and Germany is at present the leading country in the world in export trade, and her intellectual life seems as keen as ever. Man might conceivably destroy his present civilisation by persistent internecine warfare, but the task becomes increasingly difficult.

IN the presence of representatives of the Italian Government, an official demonstration took place on Nov. 20 in Italy between Santa Margherita Ligure and Levanto—a distance of 25 miles—of the new Marconi quasi-optical, ultra-short wave radio-telephone system. The wave-length used was only 50 cm., the same as that employed in the previous demonstration recently carried out between Santa Margherita Ligure and Sestri Levante over a distance of 11 miles, corresponding to a frequency of six hundred million cycles per second. The success of the demonstration was all the more complete because, although the range had been increased from 11 miles to 25 miles, the margin in the signal strength was such as clearly to indicate that the apparatus was capable of covering a considerably greater distance. This demonstration is a test of a new practical and commercial radio system which will very shortly be used for public services in Italy. Owing to its simplicity the new system is very moderate in price and in running costs: it will thus soon afford to the inhabitants of many small islands scattered in the Mediterranean a reliable telephone service, with a range at present of about a hundred miles, which they could not, heretofore, enjoy in consequence of the high cost of the submarine cable telephone installation.

THE progressive extension of the grid by the Central Electricity Board has led many dwellers in rural districts of Great Britain to hope that in the near future they may be able to get the electric light at a reasonable cost. In a paper by E. W. Dickinson and H. W. Grimmitt read to the Institution of Electrical Engineers on Nov. 19, the problem of rural electrification was thoroughly discussed. They conclude that if the density of the population in a rural district of about 400 square miles in area be not much less than a hundred, then there is no financial or technical reason why this supply should not be given. Under average conditions, they see no reason why the price should exceed a flat rate of about sixpence per unit, but they advise charging a fixed annual sum and a small charge a unit for the load consumed. If the population be scattered uniformly over the area, electric energy would be more expensive than coal, paraffin, or wood. Fortunately, in Great Britain most of the population is congregated in villages and hamlets. The remainder is located in country residences, institutions, farms, factories, etc., of sufficient size to warrant the capital expenditure needed to form an interlinked system of supply for the whole area. The authors' study of statistics has brought out the interesting fact that any lowering of the price to the consumer results in an increase of revenue. At the higher rates of charge, a given percentage drop in the price produces only a small percentage increase in the revenue; but at the lower prices the same percentage drop produces a remarkable increase.

The rapidity with which the number of high-power broadcasting stations is increasing in Europe is causing anxiety to radio engineers. In the spring of 1929 there was only one transmitter in Europe having a power of 50 kilowatts. There are now nearly thirty. Although it is only two years since the European Postal and Telegraph Administration met at Prague and formulated the wave-length plan known as the Prague Plan, based on a nine kilocycles separation between stations, it is now obvious that it needs alteration. It will be remembered that at the opening of the Stuttgart-Mühlacker Station in November 1930 the interference between it and London Regional was very serious. Fortunately it has been possible by experiment to make certain slight modifications in the frequencies of several British stations so as to avoid interference in certain specific cases. In some instances the bands of frequency have been separated by eleven kilocycles. It is obvious that if no limit is fixed to the power radiated from a broadcasting station, several of the channels of communication allotted to countries internationally must be sacrificed. It is because certain nations refuse to consider such sacrifices that no decisive action was taken at the meeting of the International Broadcasting Union (U.I.R.) at Rome in October. We learn from *World Radio* for November that the B.B.C. has carried out a large number of experiments, both in the laboratory and under practical reception conditions, at its receiving station at Tatsfield, to ascertain how interference can be remedied. It appears clear that, beyond a certain point, improving selectivity decreases the quality of the reproduction. Similar results have been obtained by Dr. Van der Pol in Holland. There is little chance of any step being taken in the direction of establishing a new wave plan before the international meeting at Madrid in the autumn of 1932.

An attempt is shortly to be made by the State Radiological Institute at Prague to evaluate the radioactivity of the atmosphere in different parts of Czechoslovakia. The object of these investigations, which have the support of the Czechoslovak Ministry of Health, is to discover whether there is any noteworthy difference between the radioactivity shown by the atmosphere in the neighbourhood of the spas such as Karlsbad, Marienbad, Poděbrady, Jáchymov (where there are extensive uranium mines and the ore is worked up for radium preparations, etc.) and that of the general countryside and town air. The radioactivity of the atmosphere at the climatic resorts in the Giants' Mountains and the High Tatras will also be studied for comparison. It is suggested that the radium emanation in the atmosphere must exert some therapeutic action, perhaps comparable with that of sunlight or warmth. Indeed, Prof. J. Stoklasa has gone so far as to declare that this radioactivity may play an important rôle in connexion with metabolism, since animal organisms show a distinct radioactive content. The 60-80 gm. of potassium present in an adult exert a feeble β-and γ-radiation. Preliminary measurements, using Gerdien's apparatus, have indicated that the conductivity of the atmosphere at Prague is $0{\cdot}4\text{-}1{\cdot}2 \times 10^{-4}$ electrostatic units, whilst around the west Bohemian thermal spas it varies between $1{\cdot}0$ and $1{\cdot}2 \times 10^{-4}$. At Jáchymov (St. Joachimsthal), in the neighbourhood of the radium extraction laboratories, it is $2{\cdot}4\text{-}2{\cdot}6 \times 10^{-4}$.

On Dec. 3, 1929, at the invitation of Sir Harold Boulton and Sir James Calder, a meeting was held at the Hotel Metropole, London, for the purpose of inaugurating a Wood Preserving Association. The Association came into being, and the first number of the *Journal of the British Wood Preserving Association* marks the end of the first year of the Association's life. As is to be expected, there is not, for the expert, much original matter in the number; but it is hoped that in the future the scope of the journal will be enlarged to include original articles, reviews of current literature, and an account of the numerous other activities by which the Association is endeavouring to fulfil the purpose for which it has been formed. With Sir Harold Boulton as president, Lord Clinton and Sir James Calder, vice-presidents, and a strong council, the Association should be able to look forward to a very useful future. In addition to the editorial and description of the inaugural meeting, the journal has articles on the preservation of timber by R. S. Pearson, insects injurious to timber by Prof. J. W. Munro, and records of general discussions in the Association on the preservation of estate timber and the preservative treatment of building timber. Perhaps one of the most promising sides of the Association's future possibilities, from the practical point of view, is the setting up of the Technical Committee. This Committee has already had to deal with numerous and varied inquiries. Particularly gratifying, it is said, has been the interest taken in the Association abroad, in the Dominions and Colonies, which has led to several important bodies taking up membership.

We are informed by Dr. Félix F. Outes, Director of the Museum of Anthropology and Ethnography, Buenos Aires, who is well known to students of the prehistory of America for his writings on the stone age and other aspects of the anthropology of South America, that the Council of the Faculty of Philosophy and Letters in the National University, Buenos Aires, has sanctioned the reorganisation of the Museum, which was formerly known as the Ethnographical Museum, in accordance with a scheme submitted by him at the time of his recent appointment as director. The Museum will now consist of four departments: a Department of Anthropogeography, which will be in the charge of Prof. Romualdo Ardissone; a Department of Physical Anthropology and Human Palæontology, of which a director has still to be appointed; a Department of Archæology, of which the head will be Prof. Francisco de Aparicio; and a Department of Ethnography and Folk-lore, to be entrusted to Dr. Alfred Métraux. The incorporation in the Museum of the Institute of Geographical Research will enhance its standing and at the same time place it in charge of a large amount of extremely valuable material. The publications of the Museum are also to be reorganised. In future they will be classified into four categories, of which two will be strictly scientific; one will be devoted to 'diffusion' and one to popularisation in the broadest sense of the term.

THE *Veterinary Journal* for October is a special veterinary physiology number and is also of interest from the aspect of comparative medicine. Articles are contributed by Dr. A. S. Parkes on "The Co-ordination of the Reproductive Processes", by Dr. F. W. Lamb on "The Regulation of the Acid-Base Balance of the Body", and by Prof. J. Barcroft on "Stores of Blood". Dr. Piney writes on the reticulo-endothelial system, and Messrs. Crew, Miller, and Anderson contribute a note on the diagnosis of pregnancy in the mare by the Ascheim-Zondek test, which in man is claimed to give correct results in 97 per cent of cases. A total of 390 equine samples have been examined, of which in three cases only the biological diagnosis did not agree with the clinical evidence.

ONE of the largest of the giant redwood trees (*Sequoia sempervirens*) of California is the so-called Palo Alto tree at the town of that name near the south of San Francisco Bay. It is the subject of a brief historical monograph by Miss A. I. Weymouth ("The Palo Alto Tree": Oxford University Press). The author traces the earliest records of the tree back to the first Spanish explorers of California. In 1769, Gaspar de Portola camped beneath it on his discovery of San Francisco Bay, and there are several later records of the tree. Its age is not known, but in 1777 it was already a large tree with a recorded height of 137·5 feet and a ground circumference of the trunk of 15·1 feet. At present the circumference is 23 feet. Miss Weymouth believes it to be the oldest of surviving trees.

A REPORT of Science Service, Washington, D.C., states that a new method of identification has been suggested by Dr. Thomas Poole, of Washington, which may form a useful supplement to finger print and similar methods. The method makes use of X-ray photographs of the bony cavities or sinuses in connexion with the nose. Examination of thousands of pictures of these sinuses shows that in no two persons are the shapes exactly alike, and that once formed, the bony partitions of the sinus cavities never change. The tissues of the body quickly degenerate and disintegrate after death, but bones do not, so if X-ray pictures of the sinuses have been taken during life, identification would be possible long after death.

THE National Research Council of the United States has reprinted from the July issue of the *Journal of the Acoustical Society of America* the "Bibliography of Acoustics of Buildings" prepared under the auspices of the Committee of the Council in charge of the subject, by the chairman of that Committee, Mr. F. R. Watson. It extends to twenty-nine pages, and the great majority of the papers referred to have appeared in the last five years. In many cases a brief statement as to the contents of a paper is made, which is of great assistance to those who use the "Bibliography". The references are classified under the heads: general, acoustics of rooms, and sound insulation.

THROUGH the generosity of Dr. Henry S. Wellcome, a gold medal has been founded to be awarded annually by the Royal Anthropological Institute for the best anthropological research essay. It is hoped that the first award will be made in 1932. Competition will be open to candidates of any nationality.

THE Third International Congress of Sanitary Technique and Urban Hygiene will be held at Lyons on March 6–9, 1932. As on the two previous occasions, when congresses were held at Prague and Milan, the Congress will be associated with an international exhibition which will be open on March 7–20 during, and in the buildings of, the Lyons Fair. Further information can be obtained from the General Commissary of the Congress, Dr. Garin, Rue Ménestrier, Lyons.

THE British Institute of Radiology, incorporated with the Rontgen Society, will hold its Annual Conference on Dec. 2–4, at the Central Hall, Westminster. In connexion with the Conference there will be an exhibition of apparatus, organised by the Associated Manufacturers. The Conference will be opened by the Right Hon. Lord Rutherford, and Dr. A. E. Barclay will deliver the presidential address. Besides several technical papers, two lectures have been arranged—the fourteenth Silvanus Thompson Memorial Lecture by Sir James Jeans, on radiation, and the twelfth Mackenzie Davidson Memorial Lecture by Prof. Dr. Hans Holfelder, on medical, surgical, and radiological treatments of disease. Cinematograph films illustrating experiments on the inflammability of films (Prof. F. Haenisch) and the effects of radium on living cultivated tissues (Dr. R. G. Canti) will be exhibited. Two discussions have been arranged for the last day of the Conference.

MESSRS. W. Dawson and Sons, Ltd. (Rare Book Department), Pilgrim Street, E.C.4, have just issued a new part (N.S. No. 5) of their catalogue of scientific books and serials. It contains many rarities and should be seen by collectors and librarians desirous of adding to their libraries.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A sub-editor of the *British Journal of Radiology*—The General Secretary, British Institute of Radiology, 32 Welbeck Street, W.1 (Dec. 8). An assistant in zoology at the Queen's University of Belfast—The Secretary, Queen's University, Belfast (Dec. 10). A Geoffrey Duveen Travelling Student in Oto-Rhino-Laryngology—The Academic Registrar, University of London, South Kensington, S.W.7 (Dec. 31). A professor of mathematics at King's College, Strand—The Academic Registrar, University of London, South Kensington, S.W.7 (Jan. 4). A professor of philosophy at the University College of Wales, Aberystwyth—The Secretary, University College of Wales, Aberystwyth (Feb. 1). A professor of zoology in the University of Calcutta—The Registrar, University, Calcutta (March 31).

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Light of Glow-worms.

THE letter by Dr. Ramdas and Dr. Venkiteshwaran[1] on the "Spectrum of Glow-worm" will surely arouse interest in the fascinating subject of animal luminescence and stimulate photophysical research on the phenomenon. The writers note that their worm glowed only by night, could be stimulated by shaking, and that the light was apparently under voluntary control. These details I am able to supplement by other observations, which may be of value to research workers who wish to take up the subject.

In June–July 1919 I had an abundant supply of female *Lampyris noctiluca* L. from Looseley Row, Bucks. Their light was eclipsed immediately in sudden disturbance, presumably causing alarm, but could often be enhanced by concussion and always by nipping the luminous organ; though these displays were relatively transient, being succeeded by the negativism characteristic of 'alarm'. The light emitted by larvæ was more readily extinguished and less easily aroused than that of females.

Dissecting out the ventral nerve-cord, I found that crude chemical stimuli (sodium chloride, caustic soda, common acids) were without effect, but that momentary flashes could sometimes be produced by the mechanical stimulus of nipping the cord. Single induction coil shocks, if sufficiently strong, would produce momentary flashes of light, 'break' seeming more efficient than 'make'. Continuous faradisation produced a brilliant light, but my terminals were impromptu makeshifts without attempt at screening, so that I could not be absolutely sure the luminous organ had been affected by nerve-impulse and not by the current directly. Certainly, an even more vivid effect could be obtained by plunging the terminals into the tail of the insect, near or on the organ. It was possible to suspend the tail in fixative (Zenker's fluid, alcohol, formaldehyde, 5-10 per cent), and to keep the organs glowing by faradisation while fixation gradually took place. This was a very astonishing sight, and I have always hoped for an opportunity to extend these preliminary observations into a serious research. The light of isolated and crushed luminous organs could also be observed under the microscope, perhaps as a result of mechanical stimulation of residual nerves and end-organs, but sometimes in such thin smears that the effect seemed purely biochemical.

I also made up three batches to be kept—(1) in absolute dark, (2) with a little diffuse light during the day, (3) in the fullest light that could be applied at all times, namely, full diffuse daylight all day and a 60 candle-power electric light at about 3 yards at night. There were a dozen worms in each batch. At first all three batches kept the hours then current in the field, beginning to glow at 10–11.0 P.M. and ceasing at 1–4.0 A.M. After about the third day the habits of the illuminated batch began to be deranged, and after four or five days they would only glow at irregular intervals or on stimulus by shaking, which, however, was more uncertain than with normal worms. The other two batches kept their hours well until after about a fortnight, when senility and perhaps starvation began to produce their effects, the totally dark batch being the earlier deranged and producing light by day as well as night. I concluded that external light was probably not needed for storage on the lines of chemical phosphorescence, but necessary to simulate natural conditions; at the same time, there was a remarkable automatic regulation of the hours of light which was not primarily dependent on external illumination, but could be upset by unusual conditions of environment.

Mercury Line Spectrum in Fluorescence.

IT was found by Füchtbauer[1] that mercury vapour of low density, illuminated by the radiation of a mercury arc, emits all the chief lines of the mercury spectrum in fluorescence. These experiments were extended by R. W. Wood,[2] who found, in accordance with the views of Füchtbauer, that the process is one of stepwise excitation, the mercury atom being raised in the first instance to the $2\,{}^3P_1$ state by absorption of the resonance line, and next to, for example, the $2\,{}^3S_1$ state by absorption of 4358. Emission of the visual triplet $2\,{}^3P_{012} - 2\,{}^3S_1$ then follows. Wood was able to verify this explanation by using an independent source to supply 4358.

No doubt is here expressed that this is in the main a correct account of what happens under the conditions used by these experimenters. I find, however, that when excitation is *by the resonance line alone*, and the other lines from the original source are suppressed by appropriate filters, it is still possible to observe the emission of these other lines in mercury vapour of, say, 2 mm. pressure. Thus a chlorine filter of 40 cm. thickness is absolutely opaque to the lines 3650, 3126, and 2967. Yet these lines are emitted when the vapour is excited through such a filter. Whatever the process may be by which the vapour is raised to the $3\,{}^3D_{321}$ state, it cannot be stepwise absorption, because the appropriate frequencies are not there to be absorbed. It is remarkable that the atom is raised to a level of 8·8 volts, whereas the excitation directly applied is only 4 86 volts.

I find, further, that in a rapid current of vapour the emission of these lines continues, even when the vapour has passed out of the region directly illuminated.

Much further work will doubtless be required to interpret these results. They are probably to be connected with the known ionisation of the vapour by the resonance line.

A Connexion between Fluorescence and Free Neutral Radicals.

MODERN physical theories[1] treat the fluorescence of all substances as the re-emission of previously absorbed radiation during the return of a chemical molecule to a stable form from an activated form, possessing a mean free life of 10^{-8} to 10^{-9} second. Since it has been shown that, in any atom, only the outermost, or valency, electrons are concerned in the absorption or emission of light waves of the visible order of frequency, it follows that fluorescent emission is necessarily concerned with the *re-formation of stable valency bonds* (or possibly stable 'lone-pairs' of electrons) from previously activated molecules.

Now, the photochemical activation of such simple molecules as the halogens has been *thought*, by Bodenstein, Franck, and others, to consist in the separation of the diatomic molecule into free neutral atoms of sufficient energy content either to enter into direct chemical combinations with other free atoms or radicals, or alternatively to initiate 'chain reactions'. The halogen atoms are considered to have an exceedingly short mean free life, comparable in duration with that of a molecule which can absorb light energy and re-emit it as fluorescent radiation. Further, energy of an amount approximately equal to that available on the recombination of atoms to molecules (for example, $2I \rightarrow I_2 + h\nu$) is actually emitted as fluorescence by the halogens under favourable pressure and temperature conditions.

It seems reasonable therefore to suppose that this light-energy emission might be associated with the chemical action of recombination of the neutral free atoms to the diatomic molecules. This speculation may be extended to other cases of fluorescence, and perhaps absorption of light by molecules followed by fluorescent emission might in general be concerned with the dissociation of a covalent bond into free neutral radicals, followed by recombination of these radicals once more. The emission of a fluorescence might then indicate that the dissociation of a covalent bond in a molecule had previously occurred.

For the fluorescence produced by cathode rays, the isolated electrons are obviously the equivalent of the free radicals.

Support for this suggestion is afforded by the following considerations:

(*a*) The fluorescence of sodium and mercury vapours is definitely associated with the neutral diatomic molecules Na_2 and Hg_2.[2] These can obviously be produced only by the association of single atoms.

(*b*) Fluorescent inorganic molecules can dissociate into free neutral radicals, as NO.

(*c*) The well-known inhibition of fluorescence by added substances can only be brought about by those compounds (for example, iodide ion or O_2) which can easily lose *an* electron:[1] these same substances also inhibit photochemical reactions by terminating chain processes, and combine instantly with known free radicals.

(*d*) Only certain classes of organic molecules, possessing aromatic ring systems and of unsaturated structure, are fluorescent,[3] and *all these compounds are capable of yielding free radicals* either by dissociation or by addition of the alkali metals (for example, xanthyls, *meso* anthracene derivatives, metallic ketyls, anils, etc.).

(*e*) All aromatic compounds, even if not otherwise fluorescent, give characteristic Tesla luminescence spectra, the seat of which is the aromatic ring, and which, it has already been suggested, is associated with the tautomerism of the valency bonds between the two specific 'Kekulé' phases.[3] Any such isomerisation, however depicted, must involve fission of valency bonds, with subsequent reunion of momentarily existing free radicals.

Other examples of chemi-luminescence seem capable of interpretation in accordance with the above suggestion, which it is hoped to develop further. The author is indebted to Dr. J. T. Hewitt for encouragement in submitting this speculation for publication.

Matter: Life: Mind.

BEFORE bio-chemists knew much about the chemical contents of a fertilised ovum, and especially before physicists knew anything about the size of chemical atoms, it was possible to think that the whole of the complication of an adult animal was potentially represented in such a cell. I venture to assert that the fertilised germ cell of a higher animal *in no way* contains potentially represented in it, in terms of the nature and configuration of the chemical atoms, even the outline design of vertebrate anatomy, let alone such details as the marvellous structure of the retina of an eye.

All it can possibly be is the material-to-start-on with which some non-material entity begins the work of clothing itself with a physical duplicate of its own non-material nature. This should be evident since the germ cell begins its development by dividing into two, for which its contents first practically go into solution, so there can be left no possible potential representation of the adult creature it will develop into.

The evidence points to the fact that the *energy* such an entity can exert on the germ cell is very minute compared with the energies associated with physical matter. If so, the entity could only manipulate chemical molecules that are in a state of delicate equilibrium, as is the case in the germ cell. Perhaps it can directly do no more than move electrons that are very lightly held in equilibrium. It could thus move matter only as a driver can move a locomotive, namely, by moving the starting handle.

If this is so, we can see why it is necessary that the physical body should be primarily a 'prime mover', since it must itself develop all the energy (minus perhaps a trillionth part) which the creature puts forth through it.

Biology is thus *not* the 'science of life', but only a study of the prime movers with which, in this world, life has to work through. The science of life is psychology, not biology; and psychology has in recent years seen that its fundamental subject matter is the motives and 'intentions to realise the ends they desire to realise' which living beings possess.

ALBERT EAGLE.

The University, Manchester,
Nov. 11.

PROF. BOYCOTT'S significant suggestion (NATURE, Oct. 24, p. 727) that the 'events of life' may be quantitatively out of proportion to the *perceptible* matter makes plausible the existence of *imperceptible* matter. For if we accept the idea of General Smuts, that matter, life, and mind are three grades of the same thing, we are logically entitled to describe that *same thing* by any of these conventional connotations, which become interchangeable terms denoting different aspects or principles of one 'matter', one 'life', or one 'mind'.

Are not these grades, in effect, the old 'kingdoms' —mineral, plant-animal, and man? And are not their outer distinguishing characteristics due to inner modifications of the *same thing*—a universal electromagnetic activity? If photosynthesis be essential to maintain biological existence, 'energy' and 'life' must be the same thing. Again, energy or motion implies that something is moving, however imperceptible. The polar action in chemical 'affinity' is as mysterious and imperceptible *per se* as the *selective* electromagnetic activity of biological organisms, and no less inscrutable than is the power of selection or choice exercised by means of the human brain. In minerals the polarity is superficially stable, and, therefore, *matter* is prominent; in biological forms the energy-aspect is apparently more active and *life* is more evident; in the human kingdom the selective power functions through a wider gamut than the instinctive intelligence of animals, and *mind* predominates.

As this polar function does not refer to 'size', its matter-aspect must be of a different tenuity than 'matter' so called, and hence imperceptible to us before it is precipitated or condensed into concrete states.

The supposition of an evolution through these grades is as fantastic in the present state of scientific knowledge as the ancient Hermetic axiom, "The stone becomes a plant, the plant an animal, the animal a man, and man a god". Such a process implies interacting *cycles* of evolution producing modifications of the *inner* 'structures' of bodies in the successive grades. The conception of the ancients was that evolution is a progressive functioning of the mysterious polar principle actively *synthesising* more and deeper fields within a single organism. W. W. L.

THE presidential address of Dr. H. H. Dale on "The Biological Nature of the Viruses", in NATURE of Oct. 10, puts clearly one aspect (the pathological one) of substances that may possibly lead to the most notable juncture in contemporary thought. General Smuts—and he is but one of several—adumbrates, in his holism, a synthesis of mental with physical science. The viruses, including as they do the minutest particles to which life is attributed, give promise of leading to such a synthesis. Some appear to be so small that they raise the question whether, in their series, life does not exist in sizes below any protein molecule. This class of questions is at present engaging much attention in America and Germany, and some investigators postulate the hydrogen atom as perhaps a member at the lower end of the series of living things. Dr. Dale, of course, does not consider this point. If such a view should obtain general acceptance, the notable juncture would occur *that the two greatest lines of modern thought—the evolutionary biology of Darwin and the physics of Newton and Faraday—would find a common meeting point in the atom.*

May I presume to mention that I[1] and others have tried to show that directivity and affective feeling are inherent in the processes of evolution. If so, it is fair hypothesis to attribute these to the atom, if ever it is adopted as a member of the series of living things. Dr. Dale, in his acutely logical treatment of the new facts, makes some sound remarks, one of which is: "Let us recognize that the evidence is not perfect, but beware of a merely sterilizing scepticism". A Two-Dimensional Space Lattice?

ON cooling a warm aqueous solution of dimethylthallium iodide, or on adding a ten per cent solution of potassium iodide, preferably slightly alkaline, to its cold saturated aqueous solution, part of the thallium compound separates on the surface in a regular pattern. Each crystal is equidistant from six others. The size of the pattern varies, being smaller the more rapidly crystallisation is allowed to take place. The effect is not permanent; after about half an hour the arrangement breaks down and the crystals group together in irregular aggregates, which collect at the sides. In a slightly acid solution the regular arrangement breaks down in a few seconds. I should be glad to know if other similar effects are known, and also to be given an explanation which I am unable to supply.

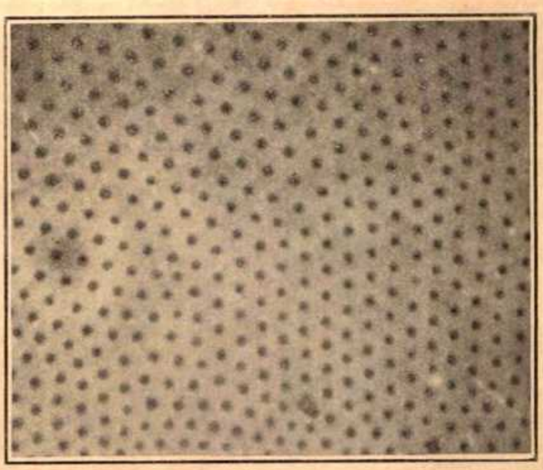

FIG. 1.

Fig. 1 is an enlargement of part of a photomicrograph, kindly taken by Dr. W. J. Elford by focusing on to the surface of a small quantity of the solution allowed to crystallise on a microscope slide.

Coagulation of Colloids by Electrolytes.

ALTHOUGH the impurities present in a colloid considerably modify its behaviour as regards coagulation by electrolytes, the importance of this point is still not sufficiently realised by many workers in colloid chemistry. It has been pointed out by one of us (Desai)[1] that a colloid can be made to show either normal or abnormal behaviour towards the dilution rule, namely, that the greater the concentration of a colloid, the greater the amount of an electrolyte required to coagulate it, by varying the amount of the peptising agent present in the colloid by subjecting it to dialysis.

In a recent note in NATURE we (Nabar and Desai)[2] have shown that in the case of colloidal gold the stability as defined by the flocculation value with KCl goes hand in hand with the charge on the colloid when it is subjected to dialysis. Since then we have made measurements of the charge on colloidal ferric hydroxide dialysed and diluted to different extents in the presence and absence of added electrolytes. The following is a summary of the results:

1. On the addition of increasingly small amounts of KCl and $MgCl_2$ the charge first increases and then decreases, the initial increase being greater with the concentrated sol than with the dilute one.

2. The initial increase in the charge is not noticeable with K_2SO_4, even when it is added in very small amounts.

3. With the progress of dialysis, although the charge

first increases and then decreases, the flocculation value with KCl shows a continuous decrease.

4. The charge increases on dilution of the colloid, the increase in charge of a sol dialysed for 2 days being greater than of one dialysed for 10 days—the dilutions in the two cases being the same.

In a paper which has been sent for publication the above results have been utilised to show that in the case of colloidal ferric hydroxide some of the fundamental assumptions made by colloid chemists in explaining their results of coagulation of colloids by electrolytes, namely, that (1) the charge and stability go hand in hand, (2) the charge continuously decreases with the progress of dialysis, and (3) the applicability of the general dilution rule, are justified. The abnormality in any particular case has been explained as being due to the preferential adsorption of the stabilising ions which may be present in an amount greater than that which corresponds to the maximum in the cataphoretic speed-concentration curve of the colloid with the particular electrolyte.

Application of the Simonis Reaction to Monohydric Phenols.

IN continuation of the work of Robertson, Sandrock, and Hendry[1] on the condensation of monohydric phenols with esters of acylacetic acids by means of phosphoric oxide, the following results have been obtained: *o*-cresol, *o*-chlorophenol, *o*-bromophenol, *p*-chlorophenol, *p*-bromophenol, and β-napthol on submission to this reaction give rise to 1 : 4-pyrones. Compared with polyhydric and with monohydric phenols, the behaviour of *m*-cresol is interesting. On condensation with ethyl acetoacetate in the presence of phosphoric oxide this phenol yields 4 : 7-dimethylcoumarin, but with esters mono-substituted in the α-position 1 : 4-pyrones are obtained, for example, ethyl α-methylacetoacetate gives rise to 2 : 3 : 5-trimethyl-1 : 4-benzopyrone.

In view of the recent communication of Chakravarti[2] on the application of the Simonis reaction to resorcinol (compare Canter, Curd, and Robertson[3]), it may be stated that the proof of the true nature of the products was first described by Canter in a dissertation submitted in 1930 for the degree of M.Sc. of the University of London.

Aitken Condensation Nuclei.

INVESTIGATIONS made by Prof. J. J. Nolan[1] and collaborators,[2, 3, 4] as well as Schweidler,[5] Hess,[6] Israel,[7] Wait,[8] and others, point to the importance of the part played by Aitken nuclei of condensation in atmospheric electric processes. It has been shown[2] that some of these nuclei carry single electronic charges, the remainder being uncharged. It has been claimed[2] on theoretical grounds that, under equilibrium conditions, the ratio of charged to uncharged nuclei is substantially a constant.

At the Commonwealth Solar Observatory, situated on Mount Stromlo, ten miles from Canberra, the nuclei have been classified into groups according to their mobilities. To effect this, electrostatic fields have been applied to a current of air passing through a cylindrical condenser and the resultant diminution in nuclei content has been measured with a modification of the original Aitken counter.[9]

Observations, made near the open window of an atmospheric electric hut, gave as a mean of 49 tests:

Nuclei.	Mobility, cm./sec./volt./cm.	Number per c.c.
Intermediate ions[10] N_A .	0·005	975
Large ions[11] N_B .	0·005 – 0·0005	385
Uncharged N_0 .	0·0005	810

Subsidiary tests indicated that the atmospheric small ion did not act as a nucleus in the apparatus, nor did any appreciable fraction of charged nuclei escape precipitation. The results appear to be statistically represented by the equation

$$2N_0 = 1{\cdot}12\ N_A + 1{\cdot}37\ N_B,$$

which does not indicate a constant ratio of charged to uncharged nuclei. The form of this equation was derived theoretically on the assumption that the uncharged nuclei were of two grades, N_{α} and N_{β}, the former giving rise, by combination with atmospheric small ions, to intermediate ions N_A, and the latter to large ions N_B. It has been assumed that the small ions were the agents in distributing the charges amongst the nuclei, and any action of the intermediate and large ions was negligible. The above equation indicates that on the average the specific rate of the combination of the N_A nuclei with small ions of opposite sign is 1·12 times greater than that of the small ions with the N_{α} nuclei, whilst for the $N_B : N_{\beta}$ equilibrium the corresponding value is 1·37. The average ratio of $N_{\alpha} : N_{\beta}$ deduced from these observations is 2 : 1.

Comparison of the N_A counts obtained by the Aitken counter with ion counts given by a Wulf unifilar electrometer attached to a cylindrical condenser indicates that the N_A group of nuclei carry single electronic charges. The mean of twenty observations gives the charge as $1{\cdot}0 \pm 0{\cdot}04$ electronic units.

Further work is proceeding in order to discover whether an equilibrium exists between N_{α} and N_{β}.

The Relativistic Opacity Coefficient.

THE recent paper of Prof. Milne[1] on "The Analysis of Stellar Structure" has excited great interest, and several papers by various investigators have appeared on the subject. The knowledge of the opacity coefficient for the different physical states in which matter can exist in the stellar interiors is of importance in these developments. The value of the opacity coefficient for the non-relativistic non-degenerate case was first worked out by Eddington following Kramers' treatment of X-ray absorption. The non-relativistic degenerate case has been recently treated by several authors.

The present note attempts to evaluate the opacity coefficient for the relativistic case. It is to be mentioned here that such a calculation has now been possible from the recent work of Hall and Oppenheimer,[2] and Sauter.[3] Following them the absorption coefficient works out to be in the case of Free-Free transitions

$$K_\nu = \frac{1{\cdot}9 \times 10^{-22} z^3 h^2 ckT}{2m\pi^2 e^4 \nu} \, \frac{e^{h\nu/kT}}{e^{h\nu/hT} - 1} \log \frac{1 + A}{1 + Ae^{-h\nu/kT}}$$

where A is the degeneracy discriminant and the rest of the symbols have their usual meaning.

When $A << 1$, $K_\nu = \frac{1{\cdot}9 \times 10^{-22} z^3 h^5 c^4}{32m\pi^3 e^4 k^2 \nu} \frac{n}{T^2}$, and taking the mean after Rosseland the opacity coefficient is

$$K_2 = \frac{1{\cdot}9 \times 10^{-22} z^3 h^6 c^4}{160m\pi^3 e^4 k^3} \, \frac{n}{T^3}$$

n denotes the electron concentration.

When $A >> 1$, $K_\nu = \frac{1{\cdot}9 \times 10^{-22} z^3 h^3 c}{2m\pi^2 e^4} \, \frac{e^{h\nu/kT}}{e^{h\nu/kT} - 1}$,

and $$K_2 = \frac{1{\cdot}9 \times 10^{-22} z^3 h^3 c}{2m\pi^2 e^4}.$$

For comparison, all the cases are tabulated below. The numerical calculations have been made for the coefficient of opacity K_2 referred to per gram of the material composed of fully ionised iron atoms (μ, mean molecular weight $= 2{\cdot}1$). ρ represents the mean density ($\rho = \mu m_H n$).

State of Matter.	Non-Relativistic.	Relativistic.
Non-degeneracy .	$3{\cdot}6 \times 10^{23} \frac{\rho}{T^{7/2}}$	$1{\cdot}1 \times 10^{21} \frac{\rho}{T^3}$
Degeneracy . .	$4{\cdot}7 \times 10^{16} \frac{1}{T^2}$	0·34

It will be seen that the above calculations are only a first approximation. The detailed paper will be published elsewhere.

National Needs.

The writer, H. E. A., of the leading article under this caption in Nature of Nov. 14 once more summons scientific workers to do something about public affairs, and to do it quickly. We are to "become militant without delay and in every quarter".

This is most stimulating; but what, precisely, are we to do? There is not a single major issue of statesmanship on which the scientific profession can speak with one voice. A very pertinent example relates to the "wise socialism" which H. E. A. evidently regards as a crucial necessity for mankind. Some scientific workers are socialists—not only 'wise', but *sans phrase*; while others are liberals or conservatives—non-socialists and anti-socialists of unimpeachable respectability.

What can we, as a profession, achieve in the world of statesmanship in face of such radical disagreement amongst ourselves? Even on comparatively trivial issues such as the Dyestuffs Act and the university franchise the profession was notoriously divided. Science is as ambiguous politically as the Christian faith.

Nevertheless, I believe that science has a contribution to make to political life over and above the indirect results of its material discoveries. That contribution is not a policy. It is an intellectual method and a temper of mind. For example, a sufficient acquaintance with scientific method might induce people to think quantitatively about public affairs. It would then be impossible for politicians to talk the sort of rubbish about the pound sterling which most of them talked during the recent election.

The scientific worker, who knows better than anyone else what the method of science means and how successful it has proved, is more concerned than anyone else to see that a due appreciation of that method is part of the cultural equipment of the citizen. This can only be brought about through a new kind of scientific education, differing from the current type in having a definite social and political reference. If he would create and sustain such an educational movement, even at some cost to himself, he would deserve still better of his generation than he does to-day.

But this can no more be described as becoming "militant without delay and in every quarter" than can the efforts of an acorn to grow into an oak.

Derived Early Mousterian (Levalloisian) Implements in the Melt-water Gravels of the Coombe Rock Glaciation.

Recently in these columns[1] I directed attention to the occurrence at Greenhithe, Kent, of flint implements of Upper Palæolithic facies in association with fragments of coarse pottery on an occupation-floor situated some twelve feet below present-day ground-level.

This 'floor' rests upon coarse gravel which overlies Coombe Rock. Both at Greenhithe and elsewhere in the locality I have since recovered from the coarse gravel (the melt-water gravels of the Coombe Rock glaciation) a series of rolled and patinated artefacts of Early Mousterian (Levalloisian) age, consisting chiefly of flakes with faceted butts and tortoise-cores. These specimens will be fully described and illustrated on a future occasion.

The deposits capping the horizon of the occupation-floor are shown on the Geological Survey Map (Sheet IX. N.E. Kent. Scale 6″ to 1 m. geologically surveyed 1920 by Mr. C. E. N. Bromehead) to be "Coombe Deposits", which on page 3 of the Survey Memoir on Dartford (1924) have been classed as "Pleistocene".

Two of my excavation-sites coincide with points specifically detailed by the Survey as:

(1) "10 to 12 feet Brickearth"
and (2) "2 to 12 feet Brickearth".

Thus, what I described as stony loam with 'rafts' of Coombe Rock, brickearth, and sand has been mapped by the Geological Survey under the comprehensive term—Brickearth.

It is of significance that the stony loam of Danes' Dyke, Flamborough Head, Yorks, described by Lamplugh as late-glacial,[2] which I have shown to contain derived artefacts of Upper Palæolithic types, has an officially recognised Pleistocene counterpart in the Thames Estuary.

Central Wyoming Pictographs.—Dr. E. B. Renaud of the University of Denver, in a special investigation report to Science Service of Washington, describes two series of pictographs in Central Wyoming not previously visited by archæologists. On a prairie trail 15·5 miles south of Moneta and 77 miles west of Casper numerous pictographs were found on much eroded sandstone cliffs, extending over a district about a quarter of a mile long. The most curious, and in fact unique, pictographs are shields or circles, mostly coloured, the principal shades still discernible being a strong green, a pale orange, and a purplish red. These disks are sometimes grouped in panels of ten or twelve. They represent conventional designs, human and animal figures, usually one in each circle or two or three, one being central and the other two smaller and artistically distributed, or arranged in quarters. For various reasons they cannot have been made less than two hundred years ago, and are perhaps older. In addition to the coloured type of circular pictographs there are many incised figures of men, animals, and conventional designs of the more generally known type of petroglyph. Some are isolated; more often they are grouped in panels. They may be more recent than the coloured pictographs. Among the animals represented are deer or elk, buffalo, antelope, small quadrupeds, others not identifiable, snakes and birds. The turtle is usually coloured, and never appears except on circular pictographs. This is an animal at present non-existent in the region. There are several styles of anthropomorph. One has pointed shoulders and the sexual parts are emphasised; the other, which is rarer, represents human figures with a bigger round face or head, no shoulders, and neck as broad as the body, which is rectangular. The arms are uplifted as in worship. A third type has shield and lance and recalls the type of Sand Creek, south of Laramie. A second group of pictographs, 19 miles south-east of Lander, consisting of realistic figures of men and animals, was also visited.

Marugin Warfare.—Warfare among the Marugin and surrounding tribes of north-east Arnhem Land is described by Mr. W. Lloyd Warner in *Oceania*, vol. 1, No. 4. It is one of the most important of social activities, and without it Marugin society as now constituted could not exist. There are six distinct varieties of warfare, and each has a distinctive name. In an additional form only the women participate. They are (1) a fight within the camp; (2) a secret method of killing; (3) a night attack in which an entire camp is surrounded; (4) a general open fight; (5) a pitched battle; and (6) a ceremonial peace-making fight, which is in part an ordeal. The first is the most frequent, but seldom results in a killing; while the pitched battle, although there have been two only in the last twenty years, has accounted for the death of twenty-nine men. The weapons used are the wooden or stone-headed spear, the throwing stick and the club. No shields are used, the throwing stick serving its purpose. White clay is used as war-paint. The most frequent causes of warfare are the desire to avenge the death of a relative; next, the stealing of a woman; then comes killing by black magic and ritual offences against a clan, such as the illegitimate assumption of a totem emblem, an insult to the clan to which the emblem properly belongs. The underlying principle is that of reciprocity, to inflict on the enemy clan a loss similar or identical with that which has been suffered by the attacking clan. Another belief centred around killing, and a frequent cause of war, is that the spirit of the dead man enters the body of the killer, giving him double strength and actually increasing his bodily size. Hence young men who wish to gain strength go out and kill. The women's fights are frequent. Occasionally more than two women are involved. The weapons used are the ironwood digging-sticks, and bloodshed is always a result.

The Pigmy Right Whale (*Neobalæna*).—In 1890 there were recorded the occurrences at various times of three individuals of this species, limited in distribution, on South Australian coasts, but although the recorder, A. Zietz, stated that photographs and measurements had been taken, no further details were given. The old MS. records and photographs have been hunted out by H. M. Hale, and appear in the *Records of the South Australian Museum* (vol. 4, No. 3, p. 314, 1931). Two of the specimens were males, 9 ft. 1 in. and 11 ft. 2 in. long respectively. Instead of 43 vertebræ, one specimen had 41, another 40, and in one, in place of the typical two lumbar vertebræ, there were three. The longest plate of baleen measured 200 mm. The third skeleton is in the museum at the University of Cambridge. In the 11-foot specimen the small intestine, from pylorus, was 132 feet long, and the large intestine, including 6 in. cæcum, 5 ft. 6 in. The photographs show well the curious elongated body of this rare animal.

A Nematode Parasite of a Lucanid Beetle.—J. R. Christie and B. G. Chitwood contribute (*Jour. Wash. Acad. Sci.*, vol. 21, No. 15, 1931) observations on the life-history of *Chondronema passali* (n. gen.), a nematode which occurs in large numbers in the body cavity of a lucanid beetle, *Passalus cornutus*, common in the eastern States of America. Nearly every beetle examined was infested with large numbers (500-1000) of the worms in various stages of growth; of the relatively few grubs examined about one-fifth were infested. A description is given of the youngest larvæ, about 0·4 mm. long, found in the body cavity and of the last stages found there, which are easily distinguished as males and females, about 3·3 mm. and 3·9 mm. long respectively. In the youngest stages the genital primordium is composed of a large anterior cell and three slightly smaller posterior cells, and an anterior cap cell was present; the subsequent stages of growth of this primordium are briefly described. The parasites enter the beetle as very young larvæ, being probably taken in during the act of feeding; it is suggested that the beetle swallows a female worm with its contained young. The larvæ moult once while inside the parent worm, and another moult probably takes place soon after emergence from the host. The method of exit of the worms from the beetle was not ascertained. *Chondronema* is related to *Atlantonema* and *Tylenchinema*, but is differentiated from all related genera by the fact that the vulva, if it functions at all at the time of copulation, becomes vestigial; it never serves for the extrusion of eggs or larvæ. The larvæ remain parasitic until full grown and the adults are free living.

The Auditory Region in Certain Extinct Mammals.—In the *Bulletin of the American Museum of Natural History*, vol. 62, 1931, Dr. van der Klaauw gives an account of the auditory region as observed in a wide series of extinct mammals, preserved in various collections in the United States. This section, however, forms a comparatively small proportion of the whole paper, not being more than some thirty out of 350 pages. The bulk of the work is devoted to what the author terms a " review of the tympanic region ", in which he treats, in considerable detail, a great number of questions arising out of an examination of the ear region in general of mammals, living as well as extinct. While there is no summary of results, there is a mine of useful information in the body of the work and a full citation of the literature.

Frost Injury to Plants.—It is natural that the *Canadian Journal of Research*, vol. 5, July 1931, should contain papers upon this subject of very live interest to the Canadian community. R. Newton and W. R. Brown, of the University of Alberta, conclude that dehydration is the basic cause of first precipitation of plant proteins rather than the pressure of the ice crystals, as suggested by Maximow. An exposure of five hours at − 7° C. caused maximum precipitation of the proteins of the expressed juice from the leaves of unhardened winter wheat grown in the greenhouse. Sucrose added to the juice acted as a protection against the precipitation; its protective value increasing with concentration up to 8 per cent, a value often attained by hardy varieties of winter wheat in the field. Similarly, sugar protected the proteins against precipitation by acids, bases, or 'salting-out'. This action of sugar seems to be of very considerable significance, although its explanation still remains obscure.

The Melting of Glaciers.—In a note written for Science Service (Aug. 26, 1931), Dr. W. J. Humphreys, of the U.S. Weather Bureau, discusses the melting of glaciers. It is often said that glaciers limit themselves to a moderate thickness because their own weight continually melts them at their base at a rate that increases with the load. He points out that though the melting point is lowered by pressure, an increase of pressure on the bottom layers does not enforce rapid melting, and would not do so, except briefly and to a small extent, even if the initial temperature there were exactly at the melting point. This is because melting requires the supply of much heat, and the very act of melting automatically cools the ice, the further melting of which is controlled entirely by the rate of supply of heat. At the bottom of a glacier even 10,000 feet thick the melting point would only be 4·12° F. below the normal value. In the case of a thick ice sheet, the supply of heat for melting must come almost solely from the earth below, and this is enough to melt only about a quarter of an inch of ice in a year. Thus the limiting thickness of glaciers must be determined mainly not by melting due to excess pressure but by other causes, such as horizontal flow, surface melting, the removal of surface snow by winds, and the reduced precipitation at high levels.

Mixing of Warm and Cold Saturated Air.—The *Memoirs* of the Imperial Marine Observatory, Kobe, Japan, contain papers in English on a variety of scientific subjects, including meteorology. In vol. 4, No. 2, there is a paper dealing with what is, strictly speaking, a problem of ordinary physics, but it is a problem of fundamental importance to meteorology. It is by K. Hidaka, and is entitled "On Mixing of Warm and Cold Saturated Air". The author follows the methods of Von Bezold for calculating the results of such mixing, according to which the two masses are first supposed to mix without condensation so as to give a supersaturated mixture, and then to begin to condense water with liberation of latent heat. This heat, of course, raises the temperature of the mixture. The problem is far from being so simple as might at first sight be supposed, owing to such complications as arise, for example, from freezing or melting of ice, the effect of pressure on the freezing point, and variations in the specific heat of moist air in accordance with the amount of water vapour therein. These are treated mathematically, the final result being a valuable set of tables giving at three different atmospheric pressures (1) the final temperature, (2) the amount of water vapour in 1 kilogram of the mixture at the final temperature, and (3) the amount of water condensed per kilogram, when 1 kilogram of air at temperature t_1° C. is mixed with 1 kilogram at t_2° C., t_1 and t_2 being taken for 5° steps from − 30° C. to + 30° C. The pressures to which these figures apply are those corresponding with 760 mm., 700 mm., and 600 mm. of mercury under standard conditions (0° C. and latitude 45°). The author proposes to deal in due course with the problem of calculating the results of an admixture of equal volumes instead of equal masses of air at different temperatures.

Changes of Intensity in the Hyperfine Structure of Lines.—A number of discrepancies have occurred in the descriptions of the hyperfine structure of spectra, different observers finding in some instances different structures for the same line. When it has not been possible to explain this by self-absorption, it has usually been inferred that some flaw in technique has existed. An investigation of certain lines of cadmium which is described by H. Schüler and J. E. Keyston in the issue of the *Zeitschrift fur Physik* for Sept. 3 now shows that the effect may be real. The lines studied were found to exhibit a difference in the intensities in their hyperfine structures according to the part of the source of light, the spectrum of which was photographed. The line at λ5086, for example, could be produced with either two or three components, the relative intensities in the pair of lines common to both cases being reversed when the third was present. Self-absorption of the light in the source is believed not to be the cause of these changes, and their origin remains completely unexplained. Whatever it may be, however, it has evidently to be taken into account in the investigation of isotopes by this method, and it is remarkable that the hyperfine structure, which is due to the quantised spin of the atomic nucleus, should be so easily influenced by causes external to the atom.

Collision Properties of Protons.—Some measurements of the mean free paths of protons, which are described by C. Ramsauer, R. Kollath, and D. Lilienthal in the *Annalen der Physik* (vol. 18, p. 702), compare in an interesting way with the results for slow electrons. With both types of particles, the mean free path changes considerably with velocity; for protons, there is a maximum in the curve showing the mean free path as a function of the velocity of the proton for four of the five gases studied (argon, nitrogen, hydrogen, and neon), and possibly also for the fifth (helium). The maximum moves to greater velocities with increase in the ionising potential of the gas through which the protons are passing, and at the maximum the mean free path is greater than its kinetic theory value, being four times as large for nitrogen, eight times for neon, and still larger for helium. For greater velocities, the mean free path again decreases, becoming, at least for the diatomic gases and argon, less than its kinetic theory value, but with argon it then passes through a minimum, and there are signs that this will also occur at higher velocities with some of the other gases. The maximum and minimum also occur with electrons passing through argon, but there is no obvious close correlation between the electron and proton curves. The energy of the proton at maximum and minimum points is much greater, and its de Broglie wave-length much smaller, than the corresponding quantities for the electron, only the linear velocities being of the same order of magnitude. The protons were produced for most of the experiments by bombarding a piece of impure metallic lithium with electrons, and were rendered homogeneous in speed and separated from other ions by magnetic sorting after acceleration in an electric field.

Oxidation of Ethylene.—The slow oxidation of ethylene was studied by Bone and R. V. Wheeler in 1904, who found that formaldehyde was produced as an intermediate product, and Blair and T. S. Wheeler in 1922 showed that acetaldehyde was an oxidation product, in one case half the ethylene oxidised being converted to this product. In two papers in the October number of the *Journal of the American Chemical Society*, Lenher describes extensive experiments on the slow thermal oxidation of ethylene in various types of apparatus. The reaction is mainly homogeneous and of the chain type, the velocity being dependent on the third power of the ethylene concentration and practically independent of oxygen, in agreement with experiments of Thompson and Hinshelwood in 1929. Among the products of reaction at high temperatures and short times of contact, with high ethylene concentrations, is propylene, so that oxygen can activate ethylene to undergo polymerisation. Oxidation products include ethylene oxide and formaldehyde formed in the early stages of the oxidation, and preceding the appearance of acetaldehyde, dioxymethyl peroxide, formic acid, carbon oxides, and water. Hydrogen peroxide is formed in the reaction, probably giving, with formaldehyde, the dioxymethyl peroxide. The paper contains a concise scheme of the mechanism of the oxidation of ethylene, which is obviously much more complex than has previously been supposed.

Synthesis of Anthocyanins.—The *Journal of the Chemical Society* for October contains eight papers by Robinson and several co-workers on the synthesis of anthocyanins. It had previously been shown by synthesis that callistephin chloride is 3-β-glucosidyl pelargonidin chloride, and the first of the present papers deals with the synthesis of 3-β-glucosidyl cyanidin chloride by an analogous method, and the proof that it is identical with chrysanthemin chloride, the latter being probably the same as asterin. The results involve the attribution of the 3-bioside structure to mesocyanin, kerocyanin, and prunocyanin, whilst cyanin is regarded as cyanidin 3 : 5-diglucoside. The second paper describes the synthesis of the four isomeric β-glucosides of pelargonidin chloride. Pelargonenin chloride, the product of the partial hydrolysis of pelargonin, is pelargonidin chloride 5-glucoside. Although pelargonin yields pelargonidin-5-glucoside on hydrolysis, and it might be concluded that the anthocyanin is a pelargonidin 5-bioside, the evidence seems to show that the position 3 does not bear a hydroxyl group. Ferric chloride in dilute solution gives with compounds containing hydroxyl in position 3 a fugitive colour, whilst compounds with hydroxyl in position 3 absent or modified give a relatively stable colour. In the third paper the synthesis of œnin chloride, from the skin of purple-black grapes, is described, and the substance is shown to be identical with 3-β-glucosidyl malvidin chloride. Succeeding papers deal with the syntheses of oxycoccidin chloride (one of the pigments of American cranberries), which is shown to be 3-β-glucosidyl-peonidin chloride; of 3-β-galactosidyl chloride, believed to be identical with idæin chloride from the cranberry, and the corresponding derivative of peonidin chloride; and of fisetinin chloride, which has alkali colour-reactions very similar to those of cyanin chloride, thus supporting the constitution of the latter advanced in the first paper. The colour-reactions of fisetinidin and luteolinidin are described, and the evidence is completed for the 3-5-diglucoside constitution of pelargonidin, cyanin, and malvin. The 5-glucoside and 5-lactoside of hirsutidin were prepared, the latter being the first diglucosidic synthetic anthocyanin obtained.

Astronomical Topics.

The Leonid Meteors.—There was no very grand display of these meteors, but a report from Mr. J. P. M. Prentice, of Stowmarket, Suffolk (who is director of the B.A.A. Meteor Section), states that he saw thirty-nine Leonids, of which fifteen were of the first magnitude, between $0^h\ 40^m$ and $3^h\ 30^m$ on the morning of Nov. 17; he thinks that the shower was increasing in strength, so we may hope for more complete reports from North America, where there is an active meteor section under the leadership of Prof. Olivier.

The Rev. W. F. Jameson, of Willesden Green, saw a bright Leonid on Nov. 16 at $11^h\ 45^m$ P.M. Mr. Prentice also saw a stray Leonid at $3^h\ 50^m$ A.M. on Nov. 14. Some of them have been dispersed to a considerable distance from the main stream.

It is to be feared that the odd quarter-day in the year will bring the rich display into daylight in 1932. This is not certain, however, as the time may be considerably modified by perturbations.

The Faint Outer Satellites of Jupiter.—Prof. M. Wolf notes in *Astr. Nach.*, No. 5819, that an object which he reported last December as a new minor planet (1930 *YC*) proved to be the satellite Jupiter VI. He gives positions of it on six days last winter, extending from Dec. 19 to Feb. 9. He also found images of Jupiter VIII on the plates of Dec. 19 and 20. He made an extended search for Jupiter VII, but without success; he has not been able to find any observations of this satellite for several years, so it appears to be lost. It will be remembered that Jupiter VIII was lost for many years, until the careful calculations of Prof. Numerov led to its recovery.

It would seem desirable to have some definite plan of observation of these faint satellites, such as has been arranged for the minor planets. This would diminish the chance of their getting lost to observers.

Nagata's Comet.—Although this comet passed its perihelion five months ago it has brightened up unexpectedly, and displayed a short tail on some photographs taken by M. F. Quénisset in October. It has remained low in the evening sky ever since its discovery, but has been assiduously observed in many countries though not in England. The late observations seem to indicate clearly that there is appreciable deviation from parabolic motion, and that the period does not exceed a few centuries. A search through the catalogues has not revealed any comet likely to be identical with it. The comet of 1804 has a distant resemblance, but not close enough to suggest more than the possibility that both were derived from a single parent comet. That comet passed near the earth, and its orbit is known with considerable precision.

No fewer than nine periodic comets are due to pass perihelion in 1932; six of these (Grigg-Skjellerup, Borrelly, Neujmin (2), Brooks (2), Kopff and Faye) were observed at their last return, so that their positions should be accurately known. Ephemerides including perturbations by Jupiter, and in some cases those by Saturn also, are contained in the "Handbook of the British Astronomical Association for 1932".

The Hakemite Tables of Ebn Jounis.

By J. H. REYNOLDS.

ON Nov. 8, 1929, the last occasion on which the late Dr. Knobel attended a meeting of the Royal Astronomical Society, he presented to the Society a rare copy of the Hakemite Tables of Ebn Jounis, translated by "Citoyen" Caussin, professor of Arabic in the College of France, An XII de la Republique (= A.D. 1804). This valuable and interesting book throws a strong light on the high standard of accuracy in observation which had been reached by the Arab and Egyptian astronomers. At the time the tables were compiled (*circa* A.D. 1000) the semi-barbaric European nations were seldom at peace, either internally or externally, and all learning had suffered grievously from civil disturbances and the neglect and ignorance of the ecclesiastical foundations. In the Near East at that time astronomy and mathematics were considered to be an intrinsic part of the education of Mohammedan princes, and astronomers were therefore often attached to their courts. It is true that astrology and prognostics were the *vera causa* of this princely interest in the majority of cases, but that did not make the observational work of the Arab astronomers any less valuable in the ultimate event.

The original Arabic MS. from which the translation was made was, and still is, in the library of the University of Leyden, and it was lent to the Institut de France by the Dutch Government of the time. There is no record of how it came into the possession of the University of Leyden, but it was undoubtedly a copy of the original MS., transcribed about seven hundred years ago. There were several copies of the work originally in the library of the Alhazar University in Cairo, and it is possible that the Leyden MS. may be part of one of these, as many of the MSS. of the library were scattered and destroyed in the repeated conquests and sackings of Cairo in the Middle Ages. Caussin was of the opinion that the Leyden MS. contained about half of the original observations made by Ebn Jounis, and that there were two volumes.

Besides a long preface, the whole work originally contained eighty-one chapters, the title of each being given in the introduction. The twenty-second chapter is the last which appears in the Leyden MS., so the greater part of the work is unfortunately totally lost to us. The titles of some of the chapters sound sufficiently modern: for example, Chap. iii., On mean time and true (solar) time—how to convert one into the other, and different methods employed by various authors of tables; Chap. x., On chords of a circle, on sines, and how to use them in calculating from the tables; Chap. xi., On the obliquity of the ecliptic, on the dimensions of the earth's shadow, and tables relative thereto; Chap. lxxvii., On radiation from the stars, according to general opinion. Other chapters introduce us to matters which, fortunately, do not affect us to-day: Chap. xv., On arcs diurnal and nocturnal; on fractions of the hour by day and night; on equal and unequal time. Chap. xvi., On the twelve houses of the sun. Chap. lxxxi., On the revolutions of the years of the earth, and on nativities.

Caussin's translation only includes the introduction and the fourth, fifth, and sixth chapters, so there is still ample work to be done in the way of translation by Arabic scholars.

An Arabic MS. in the French Bibliothèque Nationale contains the tables of the sun and moon by this author, amongst various tables taken from the works of the other astronomers. These tables form part of a work entitled "Al zij Almosthal ali", which seems to have been composed in the fourteenth century of our era. Caussin remarks: "Le titre encore plus récent qui est à la tête, l'attribue à Ebn Jounis, apparemment pour lui donner plus de prix. C'est une supercherie dont les Orientaux se servent quelquefois vis-à-vis des Européens qui achètent des manuscrits sans les lire".

Ebn Jounis came of an ancient Arab-Egyptian family. Like many of his contemporaries, he was something of a poet and a musician, as well as an astronomer. The date of his birth is unknown, but he died on May 31, 1008. There seem to have been two editions of his astronomical tables, one written about 990, in the reign of the Caliph Aziz, to whom it was dedicated, and the second, a corrected and extended series of observations, being written in the reign of his son Hakem, and dedicated to him, whence the title of the Hakemite Tables is derived.

Ebn Jounis's observatory was on a rocky spur of the Mokattam Hills near Fustat (Old Cairo), at a place called Birket Alhabash, originally a reservoir on the east side of the Nile, afterwards turned into a garden. This was probably near the old aqueduct to the citadel built by Nasir in 1311, parts of which are still standing.

In one of the Arabic texts there is mention of observations at 'Holwon', to which Caussin adds the following note: "Holwon, quelques lieues au-dessous du Caire, sur le bord oriental du Nil". This is without doubt the present town of Helwân, near which the modern observatory was erected in 1904 under the supervision of Sir Henry Lyons.

Ebn Jounis presupposed in the table a knowledge of Ptolemy's work, and his first aim was to assemble all that related to practical observation, calculation, and the use of tables. His ultimate object was to correct the tables current in his time, and his own observations were therefore of great assistance in the new tables. A quarter of the MS. is devoted to the chronology of the *Hegira*, and is omitted in the French translation, as it is comparatively unimportant. The commencement of the preface is worth translation and reproduction here:

"In the name of Allah, the compassionate, the merciful! The study of the heavenly bodies is not unconnected with religion. By this alone can be known the hours of prayer; the time of sunrise, when he who observes a fast should abstain from drinking and eating; the end of the evening twilight, the term of vows and religious obligations; the time of the eclipses, of which a man should be forewarned, so that he may prepare himself with the special prayer proper for such an occasion.

"The same study is necessary for turning in prayer always towards the Kaaba (Mecca), for determining the commencement of the months, for knowing certain doubtful days, the time for seeding, the budding of the trees, the picking of fruits, the position of one place with regard to another, and for journeying in a definite direction without straying.

"The movement of the heavenly bodies being thus allied to many divine percepts, and the observations made in the time of the Caliph Almamoun [at Bagdad] being already out of date, and containing errors similar to those made aforetime by Archimedes, Hipparchus, Ptolemy, and others, our Lord and master the Commander of the Faithful Abou Ali Almansour al imam al hakem bams Allah (May God bless him, his virtuous ancestors, and his noble descendants), has ordered me to observe anew the heavenly bodies whose movement is more or less in accord, and many of those whose progress is slow compared with the existing tables.

"First of all I assured myself of the excellency of the instruments with which I made my observations. I constructed them with greatest care, and divided them with the finest accuracy I could command. I spent much time in examining them and verifying their divisions. I compared them one with the other to assure myself of their reliability; and when I had found with certainty the places of the planets, I used, in order to determine their mean motions, the observations of the ancients, since it is in this way alone that such a correct determination can be made."

The principal instruments used by Ebn Jounis were the armillary sphere and the azimuth circle. The larger the diameter of these, the greater the accuracy with which they could be divided. Unfortunately, no details are given as to their dimensions and construction, so we have to fall back on descriptions of such instruments constructed at Cairo after the death of Ebn Jounis and contained in Caussin's notes.

The armillary sphere was a series of rings, the outer and principal one representing the meridian. Then came a movable declination ring pivoted on the poles, containing on its inner edge two other pivots 23° from the poles, and on these pivots were fixed two other rings at right angles to each other, representing the ecliptic and colures. Still another sliding inner ring with sights at the ends of a diameter enabled readings to be taken both in latitude and longitude. These were made up to 2 ft. in diameter and probably more, as the azimuth circle constructed by the order of Alfadel a hundred years later was 200 inches in diameter.

Numerous references are made in the introduction and Chap. iv. to the "Verified Table". This table was compiled by order of the Caliph Almamoun at Bagdad about fifty years before Ebn Jounis worked out his own Tables. Several astronomers were engaged in this compilation, the principal being Jahia ebn Aboumansour. An Arabic MS. of this Verified Table was, and presumably is now, in the library of the Escurial.

Ebn Jounis devotes the whole of Chap. iv. to a comparison between recent observation and calculation by the Verified Table, especially with regard to eclipses of the sun and moon. He was specially critical of tables of the sun's longitude, which he found to be largely in error. He points out that the armillary sphere of Jahia ebn Aboumansour was only divided to 10′ of arc, and was not, therefore, of the accuracy required for close determinations of the sun's place. As an example of the refinement of accuracy attempted by the Arab astronomers, Ebn Jounis cites results obtained for the mean motion of the sun in a Persian year of 365 days. The sons of Moussa ebn Shaker at Bagdad gave this as 359° 45′ 39″ 58‴ 2⁗! The division of the second into sixty thirds, and that again into sixty fourths, and on occasion even to fifths, must come as a great surprise to present-day astronomers, for a fifth was only equal to 0·0004″, a quantity representing less than probable instrumental error even to-day. Of course, the figures given were simply obtained by continuing division.

A list of conjunctions of the planets with each other and with the 'Lion's Heart' (Regulus) are given with considerable detail. One observed by Habash at Bagdad on Oct. 10, A.D. 864, was that of Mars and Venus in Virgo, so close as to appear one planet. "We have obtained their conjunction in this manner in the table Alshemashia by adding to the epicycle of Venus, and to the mean motion of the sun in the table 4° 30′; next deducting from the epicycle of Mars 30′, and deducting the result from the mean motion of the sun."

Some partial eclipses of the sun visible in Cairo were observed with great interest by Ebn Jounis and his friends, who assembled at the Mosque of Aboufaafer Almagrebi for the purpose. One on Dec. 12, A.D. 977, was evidently a great astronomical occasion. The names of many of those in attendance were given, of whom he says: "These persons were instructed without being versed in the practice of judiciary astronomy (prognostics)". The eclipse was first seen when the sun was between 15° and 16° above the horizon. Its greatest phase was estimated at 8 digits (twelfths of the diameter) in magnitude. "When the sun seemed to regain all its brilliancy I found its altitude to be about 33° 20′, all being in agreement as to the end of the eclipse." Next appears a list of determinations of the vernal and autumnal equinoxes, made by various astronomers, commencing with one by Ptolemy in the third year of the reign of Antoninus Pius, at Alexandria. Many observations by Arab astronomers at Bagdad and Damascus, from A.D. 830 to A.D. 851, appear also in the text.

Chap. v. contains various determinations of the sun's mean motion in the Persian year of 365 days, almost all of them being in agreement with a value of 359° 45′ 39″, differing only in thirds. All of the astronomers arrived at their results by dividing the number of solar revolutions by the number of Persian years which had elapsed between the time of their observations and the original observation of Hipparchus. By the same method Ebn Jounis arrived at a slightly larger value—359° 45′ 40″ 3‴ 44⁗. He is especially interested in various estimates of the position of the 'Lion's Heart'. "I am going to give particulars of these differences, so that those who wish to know the science of calculation and observation of the heavenly bodies, by comprehending every difficulty and by seeing how much trouble is involved in arriving at the truth, may be more disposed to excuse errors which escape the notice of persons who give themselves up to this kind of study; and Allah conducts whom he will in the path of exactitude."

The differences in the positions of Regulus were found to range from 3′ to 33′ for the same year by interpolation from various observations made in previous and subsequent years. The Arab astronomers who contributed the results are mentioned individually and their calculated places given in detail.

Chap. vi. is entitled: "On the mean motions of the Verified Table, on its equinoxes, and on the position of its apogees: on the mean motions of the present Table, on its equations and its apogees". This chapter consists entirely of comparisons between various determinations by Ptolemy and others of the mean motions and other elements of the sun, moon, and planets and Ibn Jounis' own results. It is scarcely of sufficient general interest to quote extracts here. Caussin had evidently intended to translate and publish the rest of the Leyden MS., but this unfortunately he never accomplished. He ends the volume by giving various small extracts from other Arabic astronomical MSS., with a computation based on the Tables.

All the way through, the actual Arabic text is given on one page with the French translation on the other. The text is fully annotated with references to Arab astronomers, their instruments, and their methods of observation. Evidently, Caussin was a master both of classical written Arabic and Arab literature, and his work deserves the grateful appreciation of scientific historians.

Forest Gardens.

THE 'forest garden', as it has come to be known, consists of a group of experimental plots of different species of forest trees maintained for the purpose of obtaining statistical data of rate of growth and so forth, under uniform soil conditions. It is a pity that some term more expressive of the real nature of these experimental observation centres is not employed. 'Forest garden' can only convey to the public an erroneous idea of the objects aimed at, whilst even to foresters the use of the term is liable to considerable misunderstanding. In parts of the Continent the term 'forest garden' is applied to the demonstration area attached to a forest school. This area is maintained, partly as a botanical partly as a forestry one, for educational purposes. Groups of plants and shrubs are grown, often in strict botanical divisions; types of different species of trees may be maintained in an arboretum; and, lastly, experimental plots of trees, indigenous and exotic, are grown for the purposes of study and obtaining statistical data so far as the local factors admit. Such a centre is a true forest garden, and is so understood by foresters in many parts of the world.

The nomenclature of British forestry is still in its infancy. It may be suggested therefore that a more appropriate term than 'forest garden' might be decided upon for so important a piece of work as that carried on at the Observation Statistical Centres maintained in the British Isles. These are five in number, and the work inaugurated at each is now made available to the public in "Forestry Commission Bulletin (No. 12), Forest Gardens (1931)". The bulletin has been prepared by Mr. J. MacDonald, research officer (Scotland), partly from notes taken by himself, partly from published data. The vice-chairman of the Forestry Commission (Sir R. L. Robinson), in a foreword, gives a brief history of the forest gardens, five in number: Cockle Park, near Morpeth, Northumberland; Cirencester, Gloucestershire; Abbotswood, Forest of Dean, Gloucestershire; Alice Holt, Hampshire; and Ceiriog, Denbighshire. The areas vary in size from three acres at Alice Holt, where there are only five plots, to fifty acres at Ceiriog, with more than fifty plots and groups. The value of plots of this nature was pointed out by the Departmental Committee on Forestry, the report of which appeared in 1902. At this time only the Cockle Park area existed, planted in 1898-99 by Sir William Somerville, at that time director of the Station. There is considerable variation in the growth of some of the plots owing to the soil conditions of the areas chosen not being uniform. Cirencester plots were planted in 1903-4 and 1904-5, under the supervision of Mr. F. C. McLellan, in connexion with the Royal Agricultural College, Cirencester, thus following Sir William Somerville's example, the Cockle Park areas being designed for the benefit of the students of Armstrong College, Newcastle-upon-Tyne. The conditions at Cirencester are as nearly as possible uniform.

The chief part of the Abbotswood plots was planted under the auspices of the Office of Woods between 1904 and 1909, other plots being added later. The plots are comprised in four series, covering some 43 acres, some being of very considerable interest. The Alice Holt area was also laid out for the Office of Woods by Sir William Schlich and Dr. (now Sir William) Somerville in 1908. The Ceiriog experimental plots comprise the most extensive area and are managed by the Forestry Department of the University College, Bangor. They are the property of the Denbighshire County Council. The planting was commenced in 1907 and has been continued since. The other areas of the same type are those at Bagley Wood, Oxford, and Avondale, County Wicklow, Ireland.

Reference must be made to the bulletin for a detailed description of the different plots on the various areas, the descriptions being accompanied by statistical data, height growth curves, and some excellent photographs. On the whole this brochure is entitled to rank as one of the most interesting bulletins yet issued by the Forestry Commission.

Insect Relations of Plant Virus Diseases.

A MASTERLY review of the present stage of our knowledge of the relations between plant virus diseases and insect vectors has recently appeared. The author is Dr. Kenneth Smith of Cambridge, and the paper is entitled "Virus Diseases of Plants and their Relationship with Insect Vectors" (*Biological Reviews*, vol. 6, No. 3, July 1931, pp. 302-344). A survey of all the virus diseases yet described is first given, and all information as to their insect vectors, if any are known, is brought together. The amount of information passed under review is so large and the conclusions drawn from a consideration of it are so important that it seems advisable to give them in considerable detail.

Biting insects (Coleoptera and Orthoptera) are responsible for the spread of only one or two viruses, and the transfer is considered to be purely mechanical. Sucking insects, on the other hand, transmit many virus diseases, and the aphid *Myzus persicae* Sulz. has been known to spread fourteen viruses. A close relation between the virus and the sucking insect is usually demonstrable. There is a close specificity between the insect and its particular virus or viruses. An insect which becomes disease-transmitting does so only at the end of a short period after its feeding on a diseased plant; it is not, as a general rule, diseased or malformed itself and often retains its power to transmit until it dies. The power of transmitting a virus is not transmitted to the progeny. Male and female seem to have equal facility to become vectors, with the possible exception of the streak disease of maize, where there exists a difference between the sexes. Individual differences between the members of a species or strain exist, and there may be one or two insects which are incapable of transmitting, though all their fellows in a species or strain will spread the disease. The toxicity of an insect's saliva is not correlated with lack of power to transmit a plant virus.

The insect or the plant may be the agent in selecting a virus from a complex. Some viruses can be separated by feeding an appropriate insect on a plant infected with them, whilst a plant may take only one virus from an insect which may be transmitting two or more. The virus can in general be picked up by an insect from any part of the plant, though not always with the same facility. It is possible for an infective insect to feed on a susceptible plant without transmitting disease. A single insect is capable of becoming a vector, and takes from five minutes to six hours of feeding to acquire this faculty, and from two minutes to fourteen hours to transfer virus to a plant. Different symptoms are sometimes produced by needle inoculations from those induced by insect transfer. Insects may transmit virus from a symptomless carrier. Transmission by soil insects is considered to play a very small part in virus transmission.

The whole is an exhaustive treatment of a very complex subject, and is worthy of the attention of all workers on plant virus diseases.

University and Educational Intelligence.

CAMBRIDGE.—Prof. Albert Einstein has been appointed Rouse Ball lecturer for the year 1931–32.

At Magdalene College, Prof. David Keilin, Quick professor of biology, has been elected to a professorial fellowship.

Dr. C. G. Lamb has been re-appointed reader in electrical engineering, and Mr. T. R. B. Saunders has been re-appointed University demonstrator in engineering.

LONDON.—As the result of a consensus of opinion among representative graduates of the University, the Earl of Athlone has consented to be nominated Chancellor of the University. Other nominations have been withdrawn.

MANCHESTER.—At a special congregation on Nov. 20, the honorary degree of LL.D. was conferred upon Prof. E. Fiddes, formerly Ward professor of history, and Prof. F. E. Weiss, formerly Harrison professor of botany, on their retirement from active service and in recognition of their long and distinguished membership of the teaching staff of the University.

ST. ANDREWS.—General the Rt. Hon. J. C. Smuts, president of the British Association, has been elected Rector of the University in succession to Sir Wilfred Grenfell.

DR. J. WARD, senior lecturer in mechanical engineering at the Northampton Polytechnic Institute, London, has been appointed head of the Department of Civil and Mechanical Engineering at the Technical College, Huddersfield, in succession to Mr. J. W. Button, who is about to retire after twenty-four years' service as head of the Department.

IT is announced that the Annual Conference of the Geographical Association will be held at the London School of Economics on Jan. 6-11, 1932. The presidential address will be delivered by Sir Leslie Mackenzie on "A Health Administrator's Attitude to Geography". There will also be a discussion on historical geography, to be opened by Prof. C. B. Fawcett. Other speakers at the discussion will be Dr. J. E. Morris and Profs. F. S. Marvin and E. G. R. Taylor. Lectures are to be delivered by Mr. S. A. S. Hozayen, on the expansion of the Arabs and their contribution to geography; Mrs. H. Ormsby, on the effect of limestones on the human geography of France; Mr. J. Fairgrieve, on the use of films in teaching; Prof. P. F. Kendall, on "How Britain became an Island"; Brigadier H. S. L. Winterbotham, on new developments of the 1-in. map; and Prof. Gerhard Schott (Hamburg), on the relation of the Humboldt current to conditions on the coast of Peru. Several excursions of geographical interest have also been arranged in connexion with the Conference. There will be the usual publishers' exhibition of books, maps, and appliances, and it is hoped to have a demonstration of educational films.

Birthdays and Research Centres.

Nov. 29, 1849.—Sir AMBROSE FLEMING, F.R.S., honorary fellow of St. John's College, Cambridge, Albert Medallist of the Royal Society of Arts, fellow of University College, London, and emeritus professor of electrical engineering in the University of London.

I sent to the Congress of Physicists' meeting in Rome, on Oct. 11–18, a paper describing some researches, made during the present year, intended to ascertain if possible whether the passage of a powerful beam of light or of X-rays through a stream of moving electrons would hinder or assist it. The method adopted was to construct a Fleming thermionic valve with dull emitter filament and two wire network grid anodes, one on each side of the filament. When these anodes were kept positively charged, streams of electrons flowed from the filament to each grid. Hence, if a powerful beam of X-rays was passed transversely across the valve, the photons in this beam moved against the electron stream on one side of the filament and with it on the other. Without entering into details here, it may be said that no sensible change in the electron current on either side was found, even when the X-ray beam proceeded from a hot cathode X-ray tube with a cathode stream of 20 milliamperes. The experiments are being continued.

Nov. 29, 1859.—Sir ROBERT A. HADFIELD, Bt., F.R.S., past president of the Iron and Steel Institute and the Faraday Society; foreign associate of the National Academy of Sciences, Washington; corresponding member of the Paris Academy of Sciences; honorary foreign member of the Royal Swedish Academy, Stockholm.

In no section of science has there been more activity during the last twenty-five years than in metallurgy. In recent research on Faraday's specimens of steels and alloys made a hundred years ago, the modern metallurgist has been able to extract from these specimens (many of them weighing less than an ounce and the largest not more than five ounces) most valuable information, including full composition, by means of some five hundred chemical determinations. All this has been obtained from about 582 gm. of material. I have just completed a volume on Faraday's metallurgical researches. This book deals, among other matters, with his alloys of iron containing high percentages of platinum, rhodium, and palladium, upon which exhaustive tests have been made, showing in the case of the rhodium-iron alloy higher resistance to corrosion than any other known iron or steel alloy.

I am continuing researches made formerly with Dewar and Onnes on the effect of low temperature in increasing tenacity upon some of the iron alloys. A joint research at the University of Leyden has been undertaken by Prof. W. J. de Haas and myself, on the effect which liquid helium produces upon the tenacity of various iron and steel alloys.

One of my present researches is to ascertain whether it is possible to produce steel of high tenacity accompanied by sufficient ductility. Such material would possess about five times the strength of the latest and best mild steel containing about 0·25 per cent carbon. A steel with, say, 150 or 200 tons tenacity, and at the same time not brittle but of tough quality, would be a product of great value.

Nov. 29, 1866.—Prof. E. W. BROWN, F.R.S., professor of mathematics, Yale University, New Haven, Conn.

I am at present trying to make use of knowledge of the methods of treating gravitational problems, chiefly those of the solar system, accumulated during the past forty-five years. Lately this has led to studies in expansions, both literal and numerical, in sums of harmonic terms of various functions, but chiefly of the disturbing function. Methods for abbreviating the planetary theory form another outcome. The most important factor in the development of the gravitational history of the solar system in the remote past and remote future is, I believe, the existence of resonance relations in all such problems, and a start towards a general theory of resonance has been made. These and other developments, some already published, will be treated in a volume on the planetary theory by Prof. C. A. Shook and myself, which we hope may appear within the next twelve months. An elementary treatment of resonance with special application to the motion of a pendulum has already gone to press.

A difficult satellite problem—the motion of the eighth satellite of Jupiter—is being worked out in conjunction with Dr. D. Brouwer.

The variations in the earth's rate of rotation from year to year are being obtained with the co-operation of Dr. Brouwer and a large number of amateur and professional astronomers all over the world, by means of occultations of stars by the moon. This campaign has led to studies of the records obtained by Mr. A. L. Loomis from his Shortt clocks and oscillating crystal, which it is hoped will be continued.

During the past year a study of the problem of the prediction of an unknown planet by means of its effects on other planets has resulted in the discovery of a criterion which shows quite clearly why the existence of Neptune could be predicted and that of Pluto could not.

Nov. 30, 1858.—Sir JAGADIS C. BOSE, C.S.I., C.I.E., F.R.S., founder and director of the Bose Research Institute, Calcutta.

The results obtained at the Bose Research Institute on conduction of excitatory impulse in plants, such as *Mimosa*, demonstrate the existence of definite conducting channels between the central and peripheral parts of the leaf; direct and indirect stimulation could thus be made to act either in concordance or in opposition, which result in characteristic mechanical responses. The variation of growth induced by the stimulus of light is complicated by several factors, the individual effect of which has been determined. The modifying factors are the quality or colour of light, the energy content of the tissue, and the point of application of stimulus, constituting direct or indirect stimulation.

The characteristic effects of minute traces of indigenous plant extracts on the activity of different organs of the animal are also being investigated. Satisfactory explanation has been found of the method of capture of large quantities of fish by applying traces of certain plant extracts to the water in hill streams. Continuous records, obtained by a special automatic recorder, show that the extract has no poisonous action, but induces inactivation of the respiratory mechanism, death of the fish being due to asphyxiation.

A spectrographic method is being perfected in the Department of Chemistry of the Institute for investigating the proteolytic enzymes of plants.

Dec. 5, 1868.—Prof. A. SOMMERFELD, For.Mem.R.S., professor of theoretical physics and director of the Institute for Theoretical Physics in the University of Munich.

The electron theory of metals is being considered further with the aim of simplifying the wave mechanical treatment, especially for high temperatures. The problem of the continuous X-ray spectrum, advanced in *Ann. der Phys.*, 1931, is being studied in certain details and applied to questions of astrophysical interest. The problem of the scattering of slow electrons, treated by Allis and Morse in *Zeit. für Phys.*, 1931, is being extended to atoms of greater atomic number and to protons. The experimental researches of Dr. Kirchner concerning electron diffraction and the value of e/m are being continued.

Societies and Academies.

LONDON.

Royal Society, Nov. 19.—**J. E. Barnard** and **W. J. Elford**: The causative organism in infectious ectromelia. Appendix—filtration experiments with virus of infectious ectromelia. From mice infected with the virus of infectious ectromelia, minute bodies have been obtained, both from characteristic inclusion-bodies and by differential filtration of infective organ extracts, which are shown, in ultra-violet photomicrographs, to be minute, coccoid micro-organisms. Evidence is given that these organisms are the virus.—**V. B. Wigglesworth**: The extent of air in the tracheoles of some terrestrial insects. In the flea, mealworm, cockroach, and bed-bug, the tracheal endings normally contain fluid, as in the mosquito larva. This fluid is removed after active muscular contraction, but *not* during prolonged fasting under dry conditions. This suggests that the osmotic pressure of the blood of these insects is maintained during life at a more or less constant level (see NATURE, Feb. 28, p. 307).

Royal Meteorological Society, Nov. 18.—**J. Edmund Clark, Ivan D. Margary, Richard Marshall, C. J. P. Cave**, and **L. C. W. Bonacina**: Report on the phenological observations in the British Isles from December 1929 to November 1930. Abnormal December and January warmth and excess of sunshine in December 1929 and November 1930 made very partial amends for almost continuous adverse conditions in between, save only in June and the brief spell of glorious harvest weather which ended August. Hence for farm and garden conditions were, as a rule, bad. Spring flowers in southern parts were almost a week late. But the floral isophenes are naturally much nearer normal than in 1929. The corresponding isakairs are early mainly over southern Scotland and north-west Ireland; they are latest in west Ireland, central Highlands, and scattered English areas. Insects and birds were late.—**Sir Gilbert Walker** and **A. C. Phillips**: The forms of stratified clouds: Part 1, Experimental. Part 2, Discussion. In continuation of experimental work on vertically unstable liquids by E. H. Weber, Bénard, Idrac, and Mal an examination was made of the patterns set up in a heated liquid moving along a rectangular trough. As this did not produce vortices with their axes at right angles to the flow, recourse was had to unstable air flowing along a small wind-channel, the motion being indicated by fumes of titanium tetrachloride. By suitable increases of velocity, from zero, the patterns produced were polygons, transverse vortices, crossed vortices, and longitudinal vortices, the resemblance to clouds being more obvious than when liquids were used.—**William Dunbar**: Eighty years' rainfall at North Craig Reservoir, Kilmarnock. All but one of the dry years occur during the first forty years, while the majority of the wet years occur in the second half of the eighty-year period. The first forty years of the period were drier than the second forty. Comparing the North Craig figures with those of a gauge in the east of Scotland, and with the average for Scotland, it is suggested that the west is becoming wetter and the east drier.

Physical Society, Nov. 20.—**Miss F. Lowater**: The band spectrum of zirconium oxide. The spectrum has been photographed from λ2600 to λ8800, and bands have been found to extend from λ3200 to λ7600. The most prominent bands have been analysed into three systems, all having the same lower electronic state. Analysis of the remaining bands is in progress. —**W. A. Wood**: Lattice-distortion of cold-drawn constantan wire. A method is described for determining the variation in distortion quantitatively as constantan wire is cold-drawn, and the variation across the section of the wire during the drawing. Distortion increases quickly to a steady maximum, which is maintained despite further drawing; orientation does not begin until the maximum distortion appears; just below the surface in the less drawn wires is a region of diminished distortion, but as the wire is further drawn the degree of distortion evens out across the section (this is explained in terms of the action of the die on the surface); the temperature-coefficient of electrical resistance exhibits changes in drawing similar to the variation in distortion, and the two properties are practically proportional.—**F. Aughtie**: (1) A remote electrically recording accelerometer with particular reference to wheel-impact measurements. The instrument was developed for the measurement of the acceleration of the rear axle of a vehicle. It was necessary for the recording to be done remotely in order accurately to phase three records, two of acceleration and one of spring load. A new method of remote recording has been developed for the purpose. —(2) A remote electrically recording load-gauge for wheel-impact measurements. The load-gauge designed for measuring that component of the wheel-load which arises from the spring weight is described. —**E. V. Appleton** and **G. Builder**: Wireless echoes of short delay. An account of a simple method of producing short pulses of radio-frequency energy is given, with notes on its application in the investigation of wireless echoes of short delay. The discussion of sample records and results serves as a basis for drawing conclusions concerning the relative advantages of the frequency-change and group-retardation methods of investigating the ionised regions of the upper atmosphere.

PARIS.

Academy of Sciences, Oct. 19.—**H. Douvillé**: Some examples of evolution. In the course of work on the lamellibranchs, examples of sudden modification involving the appearance of new transmitted characters have been observed. One of the best characterised marks the origin of the Rudists. Other instances of the influence of the mode of living on the constitution of the shell are given.—**H. Vincent**: New researches on the cryptotoxins. The phenomenon of the supersaturation of the toxins by the salicylic ion. The toxin has the property of actively fixing a large quantity of salicylic acid, largely in excess of the inhibiting dose. There is supersaturation of the toxin by the chemical antibody.—**E. Mathias**: The usefulness of long periods of observation of the rainfall in a given place. A direct relation between deforestation and rainfall is proved by two sets of observations at Ambert and at the summit of the Puy-de-Dôme.—**L. Cuénot**: The athrocytary function in the Hirudineæ.—**E. Pinte**: The geometry of Hilbertian space. —**O. Boruvka**: The hypercircumferences and certain parabolic surfaces in four dimensional Euclidian space. —**F. Tricomi**: A differential equation of electrotechnics.—**G. Cerf**: A generalisation of Monge's problem.—**M. Ghermanesco**: The fundamental solutions of the n-metaharmonic equation.—**Florin Vasilesco**: The method of the *balayage* and the conductor potential of an ensemble.—**Al. Proca**: First integrals of Dirac's equation.—**D. Riabouchinsky**: The different forms of movements capable of being reproduced by the method of coloured threads between two surfaces, whether parallel or not, sufficiently close together.—**G. Blum**: Measurements of the photochemical energy of the moon obtained during the total eclipse of Sept. 26, 1931.—**J. J. Trillat** and **Th. v. Hirsch**: The diffraction of electrons by a single crystal.—**R. de Mallemann**: Molecular polarisation.—**P. Vaillant**: The constitution of solutions deduced from absorption measurements. From the spectrophotometric examination of a series of solutions of cobalt chloride it is concluded that the optical properties, although independent of the density of the chlorine ions in the medium, are slightly influenced by the simultaneous presence of foreign cations.—**R. Freymann**: The study of some liquid absorption spectra in the infra-red by means of a photoresistant cell.—**L. Dubar**: The sensibility of cuprous oxide photoelectric cells, of the type with copper grid. Comparison with the optical absorption and the photoconductivity of cuprous oxide. The experimental results are given graphically and show the variation of the photoelectric current with the wave-length of the incident radiations. The sensibility of these cells falls rapidly as the temperature of the cell rises, the e.m.f., with constant illumination, falling at 60° C. to eight per cent of its value at 15° C.—**N. Thon** and **J. Pinilla**: The deposit potentials of copper in complex solutions of cuprous halides.—**W. Swietoslawski** and **Mlle. L. Wajcenblit**: The ternary heteroazeotrope formed of carbon disulphide, acetone, and water. This contains carbon disulphide, 75·21 per cent; acetone, 23·98 per cent; water, 0·81 per cent, and boils at 38·042° C. under normal pressure.—**J. Wyart**: The crystalline networks of thomsonite and of mesotype.—**Victor Babet**: The geology of the basins of Haut Niari, Bouenza, and Haut Ogooué (French Equatorial Africa).—**Edouard Chatton, André Lwoff**, and **Mme. Marguerite Lwoff**: The infraciliary origin and the genesis of the trichocysts and trichites in the Fœttingeriideæ.—**Ch. Dhéré** and **J. Roche**: The fluorescence and especially the fluorescence spectra of pigments of the urobilin group.—**A. Paillot**: Bacterial parasitism and symbiosis in *Aphis atriplicis*.

SYDNEY.

Linnean Society of New South Wales, Aug. 26.—**T. G. B. Osborn, J. G. Wood**, and **T. B. Paltridge**: The autecology of *Stipa nitida*: a study of a fodder grass in arid Australia. Observations were made on correlation between soil type and the root system, the nature of the seed bed, and the conditions favouring germination of the seed. The influence of grazing has been studied by means of an extensive quadrat system both inside the Reserve and also in the adjacent paddocks, so that it has been possible to compare the entirely protected plants of the Reserve and those outside which have been subject to different intensities of grazing. The results of the investigation show that only by careful control of grazing during drought periods can the population of *Stipa* plants be maintained. In an area that shows degeneration of the plant cover, material benefit to the *Stipa* population is derived by leaving the area ungrazed for one or two years.—**G. H. Cunningham**: The Gasteromycetes of Australasia. (13) The genus *Pisolithus*. In structure this genus is closely related to *Scleroderma*, and is therefore grouped under the family Sclerodermaceæ of the Gasteromycetes. The genus is represented in this biological region by the two species, *Pisolithus tinctorius* and *P. microcarpus*, the former having a wide distribution through the hotter parts of the world, the latter being confined to Australia.—**J. R. Malloch**: Notes on Australian Diptera. A résumé of the known Australian members of the Piophilidæ, description of a new genus of Helomyzidæ, and some data on certain genera of Tachinidæ. The recorded occurrence of *Catharosia* is also dealt with on the basis of the material upon which it was included in the Australian list.

Diary of Societies.

FRIDAY, November 27.

Royal Sanitary Institute (at Town Hall, Sheffield), at 3.

Andersonian Chemical Society (at Royal Technical College, Glasgow), at 3.15.

Diesel Engine Users' Association (at Caxton Hall), at 3.30.

Royal Astronomical Society (Geophysical Discussion), at 4.30.

Royal Society of Medicine (Disease in Children Section), at 5.

North-East Coast Institution of Engineers and Shipbuilders (at Mining Institute, Newcastle-upon-Tyne), at 6.

Manchester Literary and Philosophical Society (Chemical Section) (at 36 George Street, Manchester), at 7.

Institution of Mechanical Engineers (Informal Meeting), at 7.

Manchester Association of Engineers (at Engineers' Club, Manchester), at 7.15.

Junior Institution of Engineers, at 7.30.

Royal Society of Medicine (Epidemiology and State Medicine Section), at 8.

Royal Institution of Great Britain, at 9.

SATURDAY, November 28.

Royal Institution of Great Britain, at 3.

MONDAY, November 30.

Royal Society, at 4.—Anniversary Meeting.

Royal Institute of British Architects, at 8.

Royal Society of Arts, at 8.—Howard Lecture.

Royal Geographical Society, at 8.30.

TUESDAY, December 1.

Royal Institution of Great Britain, at 5.15.

Institution of Civil Engineers, at 6.

London Natural History Society (Annual General Meeting) (at London School of Hygiene and Tropical Medicine), at 6.30.—President's Address.

Institution of Heating and Ventilating Engineers (Associate Members' and Graduates' Section) (at Borough Polytechnic), at 7.

Royal Photographic Society of Great Britain, at 7.

Institution of Engineers and Shipbuilders in Scotland (at 39 Elmbank Crescent, Glasgow), at 7.30.

nstitute of Metals (Sheffield Local Section) (at Sheffield University), at 7.30.

Quekett Microscopical Club (at 11 Chandos Street, W.1), at 7.30.

Institution of Automobile Engineers (at Royal Society of Arts), at 7.45.

British Psychological Society (Education Section) (at London Day Training College).—Annual General Meeting at 8.15; Ordinary Meeting at 8.30.

WEDNESDAY, December 2.

Royal Society of Medicine (History of Medicine Section), at 5.

Geological Society of London, at 5.30.

Institution of Electrical Engineers (Wireless Section), at 6.

nstitution of Heating and Ventilating Engineers (at 20 Hart Street, W.C.1), at 7.

Alchemists' Club (jointly with Glasgow Geological Society) (at Westerlands, Glasgow), at 7.30.

nstitution of Automobile Engineers (Birmingham Centre) (at Queen's Hotel, Birmingham), at 7.30.

Society of Public Analysts and other Analytical Chemists (at Chemical Society), at 8.

Royal Society of Arts, at 8.

Royal Philosophical Society of Glasgow (at 207 Bath Street, Glasgow), at 8.

Royal Society of Medicine (Neurology and Surgery Sections), at 8.30.

Royal Microscopical Society (Biological Section) (at B.M.A. House).

THURSDAY, December 3.

Linnean Society of London, at 5.

Child-Study Society (at Royal Sanitary Institute), at 6.

Institution of Electrical Engineers, at 6.

Royal Aeronautical Society (at Royal Society of Arts), at 6.30.

Institution of Structural Engineers (at Hotel Metropole, Leeds), at 7.

Society of Chemical Industry (Nottingham Section) (at University College, Nottingham), at 7.30.

Chemical Society, at 8.

Royal Society of Medicine (Tropical Diseases and Parasitology and Therapeutics and Pharmacology Sections), at 8.

Society of Chemical Industry (Chemical Engineering Group) (jointly with Bristol Section) (at Bristol).

FRIDAY, December 4.

Royal Society of Medicine (Otology Section), at 10.30 a.m.

Association of Economic Biologists (in Botany Department, Imperial College of Science and Technology), at 2.30.—Discussion on Laboratory Methods as a Means of Testing the Value of Chemical Substances for the Control of Injurious Fungi.

Royal Society of Arts (Indian Section), at 4.30.—Sir George Birdwood Memorial Lecture.

Royal Society of Medicine (Laryngology Section), at 5.

Physical Society (at Imperial College of Science and Technology), at 5.

Society of Chemical Industry (Liverpool Section) (at Liverpool University), at 6.

Institution of Electrical Engineers (Meter and Instrument Section), at 7.

Society of Chemical Industry (Manchester Section) (at Engineers' Club, Manchester), at 7.

Royal Photographic Society of Great Britain, at 7.

Junior Institution of Engineers (at Royal Society of Arts), at 7.30.—Dr. S. L. Pearce: Presidential Address.

Geologists' Association (at University College), at 7.30.

Royal Institution of Great Britain, at 9.

SATURDAY, December 5.

Royal Institution of Great Britain, at 3.

Gilbert White Fellowship (at 6 Queen Square, W.C.1), at 3.

Public Lectures.

FRIDAY, November 27.

London School of Economics and Political Science, at 5.—Prof. L. Hogben: Genetic Principles in Medicine and Social Science. (Succeeding Weekly Lectures in Michaelmas Term and in Lent Term beginning on Jan. 15.)

SATURDAY, November 28.

Horniman Museum (Forest Hill), at 3.30.—Miss I. D. Thornley: Pilgrims of Medieval England.

MONDAY, November 30.

King's College, London, at 5.30.—Prof. M. Polanyi: Atomic Reactions. (Succeeding Lectures on Dec. 2 and 4.)

TUESDAY, December 1.

University of Manchester, at 5.15.—Prof. G. Dawes Hicks: The Philosophy of Religion (Hibbert Trust Lectures). (Succeeding Lectures on Dec. 2, 8, and 9.)

WEDNESDAY, December 2.

Royal Institute of Public Health, at 4.—Prof. H. R. Kenwood: The Health Education of the Citizen.

Royal College of Surgeons of England, at 4.—Prof. F. W. Twort: The Future of Bacteriological Research (Brown Institution Lecture). (Succeeding Lectures on Dec. 4, 7, 9, and 11.)

Belfast Museum and Art Gallery, at 8.—Prof. W. J. McCallister: Adult Education.

University of Oxford.—Prof. Freundlich: The Deflection of Light in the Sun's Gravitational Field (Sumatra, 1929).

THURSDAY, DECEMBER 3.

SCIENCE MUSEUM, SOUTH KENSINGTON (in connexion with Exhibition of Modern Glasses), at 4.45.—J. W. Wilson: Safety Glass.

INSTITUTION OF MECHANICAL ENGINEERS.—J. D. Watson: The Need for More Effective Treatment of Sewage Sludge (Chadwick Lecture).

SATURDAY, DECEMBER 5.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Prof. J. R. Ainsworth-Davis: Insect Pests and their Enemies.

Congress and Exhibition of Apparatus.

DECEMBER 2 TO 4.

BRITISH INSTITUTE OF RADIOLOGY (at Central Hall, Westminster).

Wednesday, Dec. 2, at 2.30.—Lord Rutherford: Official Opening.

At 3.30.—Prof. F. Haenisch: Experiments upon the Inflammability of Films (Cinematograph Film).

At 5.—Sir James Jeans: What is Radiation? (Silvanus Thompson Memorial Lecture).

Thursday, Dec. 3, at 10 A.M.—Dr. G. Grossman: Advances in X-ray Engineering with Special Reference to High Potentials.

Dr. A. Bouwers: Economy and Quality in Radiology.

Dr. O. Bloch: The X-ray Emulsion.

W. E. Schall: Power Factor in Radiography.

C. G. Osment: Experimental Radiography Utilising the Gamma Rays of Radium.

At 3.—Dr. R. G. Canti: The Effects of Radium on Living Tissues cultivated *in vitro* (Cinematograph Film).

At 5.—Prof. H. Holfelder: Comparison of Medical, Surgical, and Radiological Conceptions in Relation to the Treatment of Disease (Mackenzie Davidson Memorial Lecture).

Friday, Dec. 4, at 10 A.M.—Discussion: The Radiation Treatment of Leukæmia.

At 11.30 A.M.—Discussion: Lipiodol in the Diagnosis of Inthrathoracic Disease.

At 3.—The Third International Congress of Radiology, Paris, 1931 (Cinematograph Film).

At 5.—Dr. A. E. Barclay: Presidential Address.

Official Publications Received.

Science and Service.

THE universal interest aroused by the Faraday centenary celebrations in spite of the world-wide economic and political unrest well attests the power of scientific biography to arrest public attention when its human aspects are adequately stressed. Beyond question, the contrast between Faraday's humble beginnings as a bookbinder's apprentice and the revolutionary effect of his discoveries on industry and on society has profoundly stirred the public imagination. The immense benefits which society has derived from the researches of this prince of investigators, no less than his unflinching devotion to the pursuit of scientific truth for its own sake, apart from all utilitarian consequences, commanded the homage of the entire world of industry and science, and have manifested to thousands of others the worth and human interest of a scientific career.

There are, of course, innumerable other scientific workers whose lives and achievements, set out so as to reveal their forceful personality and the manner in which the restless, questing spirit of science enabled them to conquer obstacles and obtain, if not always their desired haven, at least some anchorage from which humanity could start its explorations afresh, are no less pregnant with human interest. Moureu, Pasteur, Rayleigh, Ross, Fabre—the brief memoirs we have of these and many others are aglow with inspiration for those who can sense the pulsation of their fateful thought as they wrestled with Nature for her secrets.

Nor is less human interest to be found in the lives of those scientific workers who have devoted their labours to industry. Much has been written in recent years regarding the dyestuffs industry, but the full romantic story of the development of that industry still awaits the chronicler who can weave the fragmentary pictures we have of Perkin wrestling with nitrobenzene at Greenford Green, Dr. Ter-Meer at Uerdingen, or Dr. H. Levinstein's own sketches of the early growth of his father's firm, into some vivid odyssey of industry. Possibly even yet we are too near to the field of action for this task to be attempted. The great combines of chemical industry, of which almost everywhere the dyestuffs industry now forms an integral part, are dynamic and not static, and by no means represent a final phase.

There is, however, a tendency, from which not even Dr. Levinstein appears to be entirely free, to regard the great days as past, and to consider the rationalisation of industry as synonymous with the departure of initiative and enterprise. To such an assertion, made even of the field of industry represented by the manufacture of dyestuffs, the careers of such leaders as Dr. Duisberg and Dr. Engi, to cite two alone, provide a remarkable answer. Both of these outstanding leaders of chemical industry entered the dyestuffs industry as research chemists, and both were responsible for brilliant discoveries in the dyestuffs field which contributed largely to the rapid development of their respective firms. To Duisberg's discovery of the benzopurpurins and of important intermediates like benzidine sulphone must be added that of numerous other dyestuffs for which the Bayer Company has become famous, as well as the discovery of phenacetin.

Duisberg's talents as investigator, however, were combined with a personality and a vision which not only resulted in his becoming in 1925 the head of the I.G. Farbenindustrie Aktiengesellschaft at Leverkusen, but also an outstanding leader in chemical industry, whose influence was felt in the whole organisation of scientific research in Germany, in the developments which enabled Germany to reconstruct her industries to meet the difficult situations arising in the post-War years, as well as in professional associations and the training of students for industry. Similarly, Dr. Engi's scientific genius, which gave the Society of Chemical Industry in Basle thioindigo and the halogenated indigoid and thioindigoid dyes of the Ciba series, was linked to organising powers and a personality which rapidly brought him to the head of the great Swiss firm.

Other examples might readily be found, but the career of the present chairman of Imperial Chemical Industries, Ltd., Sir Harry McGowan, who entered the service of the Glasgow branch of the Nobel Co. as an office-boy; and, in the United States, Dr. A. D. Little's creation of the largest industrial consulting organisation in the world, are all the further evidence that space permits us to adduce that, even in the present industrial conditions, romance is not dead, and that there is still scope for personality and originality.

The truth is that those who view the rationalisation of industry as involving the suppression of individualism and opportunism commit the ancient blunder of regarding industry and society as static and not dynamic, and are in the company of those who saw in the passing of mail armour, the stage coach, the sailing ship, the windmill, the end of decency and order. Even on its narrowest scientific and technical side, industry is constantly changing, and every technical advance tends to bring other changes which little by little bring new demands and confront industry with fresh problems of supply. So have the growth of the rayon industries and the lacquer industries made fresh demands on the dyestuffs industry, and the relation of these industries, and particularly the lacquer industry, to the development of the automobile industry is sufficient evidence of the rashness of attempting to prophesy the demands which will be made upon any industry two or three decades hence.

Apart from this technical aspect, rationalised industry itself offers a challenge to personality which is missed by many superficial observers. These see in the magnitude of the combine a security which they assume was not possessed by the smaller firms of a previous generation, and conclude that individualism and initiative will wither for want of stimulus. The very care with which the progressive rationalised undertakings provide for the welfare of their employees tends to blind these observers to the fact that size does not affect the dependence of the large combine for security upon the same law of service as the individual and smaller firms from which it has grown.

Rationalisation of industry is only a means to render more effective service under modern conditions, and such service will not be continuously rendered unless originality and personality find their full play in the direction of the large combine and ensure that its policy is not stereotyped but develops to meet the changing needs of the world. Service, not security, is the goal, and if prizes are greater in the larger enterprise, the possibilities and consequences attending a blunder in management can equally be more serious. New methods have to be elaborated, forecasting and planning to be attempted on a larger scale, and not even in these days can an adventurous spirit be diverted from the successful conduct of industry. The great prizes of industry as of life are never to the safe and prudent, but to the adventurous who are willing to sail the uncharted seas, who take risks and know that they take them. In the fields of industrial and economic co-operation which open before us to-day, in the planning of industry on a national and an international scale so as to avoid the recurrence of such depressions and economic crises as we are at present experiencing, no less than in the complex reactions of scientific discoveries and their technical applications, there is scope for man's noblest intellectual and moral gifts in securing control of his environment.

Progressive Biology.*

By Sir FREDERICK GOWLAND HOPKINS, Pres. R.S.

IT is not going too far to claim that recent progress in experimental biology, though to a superficial view less impressive, has been not less significant, and indeed not less revolutionary than the progress of modern physics. I might support this claim in many ways. It is, I think, justified in that region of knowledge where cytology and genetical studies meet. The progress and the significance have become the greater since it was recognised that the material units of characters—the chromosomes and subdivisions of chromosomes—are 'determinants' rather than 'carriers' of genetic factors.

This domain of disinterested science is making many practical contacts. To mention but a single recent instance: Prof. R. C. Punnett, one of the original discoverers of the phenomenon of sex-linkage in inheritance, by applying his expert knowledge of that phenomenon, has produced what may be called a synthetic fowl, of which the qualities are such as to make it of extreme value to the now highly important industry of poultry breeding and egg production. The bearing of the same body of knowledge upon human affairs has been recently very ably discussed by Prof. L. T. Hogben.

The phenomena of heredity were long the stronghold of those who cling to the obscurantism of vitalistic doctrines. Infinitely complex as of course they are, we have now abundant proof that they are susceptible to analysis and that to-day they are yielding their secrets to well-controlled experimental studies. The results of these are becoming quantitative and are even yielding material for mathematical treatment, as the interesting writings of Dr. R. A. Fisher and Prof. J. B. S. Haldane have shown.

Another region in which accurate experimentation has removed, and is continuing to remove, inhibitions due to obscurantist assumptions is the physiology of the nervous system of vertebrates. It is, perhaps, too late in the day to refer to the work of Pavlov upon conditioned reflexes, though it is justifiable to emphasise its still growing influence upon thought. The work is a supreme proof of the success of the experimental method in analysing even such apparently transcendental phenomena as those which underlie the higher functions of the brain.

The nature of the transmission of events in the nervous system is receiving much illumination from the work of the Royal Society's Foulerton professors. Prof. E. D. Adrian, having developed a most admirable experimental technique for the purpose, is studying the nerve impulse and its origin with highly profitable results. He and his colleagues are now able, with great gain, to work with single nerve fibres and single isolated end organs.

A striking circumstance, brought to light by Adrian's work and that of his colleagues, is that the nervous structures so far examined exhibit such physical regularity in their behaviour that results can often be predicted within about one per cent. His experiments on animals have shown how the phenomenon of a grading in the contraction of muscles is controlled by the frequency of impulses sent out from the central nervous system, and by the number of nerve and muscle fibres involved. Moreover, he has been able to observe the activity of a single nerve cell in his own spinal cord by needle electrodes placed in his muscles, and finds human voluntary contractions are regulated in exactly the same way.

Further, Adrian has found that slow potential changes occur in nerve cells and that these are connected with their discharge of impulses; so far this work only extends to isolated nerve ganglia from insects and to nerve cells in the brain stems of fish, but the phenomena he has found are extremely significant, and it seems possible that changes of potential may be of fundamental importance in the activity of nerve cells.

Adrian has found that damaged nerve fibres set up impulses at very high frequencies, and these perhaps play an important part in sensations of pain, though his more recent work has made it clear that impulses in the smaller slowly conducting nerve fibres must also be concerned in the physical mechanism responsible for pain. A most striking feature of all this work is the general similarity of behaviour of nervous structures from whatever animal they may be taken.

Prof. A. V. Hill is studying the nerve impulse from the point of view of the thermal phenomena which accompany it. So small, of course, is the heat production in the nerve that its measurement, like that of the potential changes, calls for great refinements. It is becoming clear, though we do not yet know the details of its nature, that the nerve impulse consists of a transmitted physico-chemical event, probably involving changes of ionic concentrations at membranes with consequential changes of electric potential; the whole cycle of events, comprising activity and recovery in the nerve, being supported by the energy derived from metabolic oxidative processes which, very small in scale, are associated with the cycle.

When we hope for an increase in our knowledge of the nervous system we are always accustomed to look to researches from the laboratory of Sir Charles Sherrington. An extended study of reflexes has shown that the centripetal impulses do not pass straight through the spinal cord, but at central stations in the cord they are transformed into an enduring excitatory state, which may in turn set up fresh nerve impulses yielding the reflex discharges. The nature of this central excitatory state is being studied and will link up, I think, with some of Adrian's observations upon cell potentials.

It has long been suspected that when a sympathetic nerve is stimulated, adrenalin is liberated at the nerve ending, and that the observed effects are immediately due to the action of that substance. Now Dr. H. H. Dale, in conjunction with a member of his staff, Dr. Gaddum, has investigated the case of the para-sympathetic nerves, the influence of which in general opposes that of the sympathetic group, and has obtained good evidence that when one of these is stimulated, the substance acetyl-choline, previously existing in some inactive form, is liberated at the nerve ending. The action of acetyl-choline when injected into the circulation resembles in general the effect of stimulating para-sympathetic nerves, and there is every reason to believe that the physiological activity of the substance, rather than the transmitted physical impulse itself, is immediately responsible for the observed effects of stimulation. I may say that Otto Loewi, of Graz, has shown that when the heart beat is inhibited by vagus stimulation, acetyl-choline is actually formed in the organ, and the same substance, when artificially injected, is known to produce effects like those of the vagus.

---

* Excerpts from the presidential address at the anniversary meeting of the Royal Society on Nov. 30.

In rather unexpected circumstances we have thus brought before us an example of specific physiological effects due to the influence of the specific structure of an organic molecule. Such effects and such relations are being demonstrated in increasing diversity as fundamental factors of organisation in the animal body. This is illustrated most strikingly, of course, in the domain of the control of its activities by a group of hormones. We find in the cases of adrenalin and thyroxin, the constitution of each of which is accurately known, widely different influences depending on differences of molecular structure.

I may logically pass from hormones to devote a few words to vitamins. We now possess proof that vitamin A is closely related to the carotenes, and this knowledge may well lead, without long delay, to the artificial synthesis of the vitamin itself. With respect to vitamin D, it seems probable, if not yet quite certain, that its artificial production is already accomplished. Some four years ago the constituent of animal and vegetable substances, which is converted into the antirachitic vitamin D by ultra-violet radiation, was identified as ergosterol by Rosenheim and Webster at the National Institute for Medical Research, and concurrently by Windaus in Göttingen. A team of workers at the National Institute, led by Dr. R. B. Bourdillon, appear now to have arrived at the next stage, of isolating the vitamin itself, in crystalline form, from the mixed products of irradiation; and Prof. Windaus, following with his co-workers a different route, has again arrived simultaneously at the same goal.

There is no doubt that the substance which the British group now term 'calciferol', and which they have isolated as a dinitrobenzoate from the mixed product, is identical with the 'vitamin D_2' which Windaus and Linsert obtained by a different method; and there is little doubt that this substance, as obtained in either laboratory, is the essential vitamin D in a state of practical purity. One milligramme of calciferol has an antirachitic activity corresponding to 40,000 of the newly accepted international units.

Before I close I would like to refer to a certain aspect of the chemical dynamics of living cells, concerning which progressive studies have been made during the last few years. The cell is, of course, a seat of catalysed chemical reactions and would seem to possess a multitude of catalysts each highly specific in the influence it exerts. In the case of reductions and oxidations, however, there are other agencies of less specific activity which promote the final stages of oxidation. Of great interest among these are certain combinations of metallic iron with pyrrol groupings. One such compound is concerned, possibly with the intervention of yet another, in bringing molecular oxygen into the field of activity. What, however, is specially interesting about these associations of pyrrol groupings with a metal is the wide extent of their biological functions.

We have long known, of course, of the presence of one such association in the chlorophyll molecule, where it functions as part of the trap for solar energy, and we have been long familiar with the presence of another in hæmoglobin, where its function is to hold oxygen during its transference from the lungs of vertebrates to their tissues. Further, we now know that, within the tissues, two others promote oxidation, and yet a third prevents by its presence any deleterious accumulations of hydrogen peroxide. For adjustment to each separate function there is some slight modification of a fundamental structure. Compounds of the type in question are found in many of the lower organisms. Just as Nature seems to have hit upon sound principles for nerve structure early in evolution, so she seems to have satisfactorily chosen, very early, the chemical materials for life. This same suggestion is carried by all the more important constituents of living stuff; fundamentally the same throughout, yet always with minor differences underlying specific morphological differences.

To return to cell dynamics. Knowledge of enzymic catalysts which, with highly specific relations, activate in a certain sense the molecules which are to suffer oxidation, is almost daily accumulating. It is because this specific activation must precede oxidation that the indiscriminate action of oxygen on the living cell is prevented. Although an understanding of the complex organisation of chemical events in the living unit is far beyond our present powers, we are, I think, beginning to see what kind of organisation it may be.

One last word, however. We have assumed that the living cells we have best known are the ultimate units in biology. But of late years the viruses have forced themselves into our thoughts. What are viruses? Do they merely simulate some of the properties of the living? Can we conceive of them as something between the non-living and the living? Are they alive? We do not yet know. Research upon them is at any rate intensely active at the moment. Its results may make it necessary to modify some fundamental biological concepts, and indeed be as revolutionary in their effects as the breaking up of the atom.

A Century of Meteorology.*

By Sir Napier Shaw, F.R.S.

THE progress of the science of meteorology to the evolution of the weather-map and beyond that to the introduction of broadcasting, which makes its treatment a matter of universal interest, can be traced from the unco-ordinated efforts of private observers, which were criticised in a report to the British Association in 1832 by J. D. Forbes, professor of natural philosophy in the University of Edinburgh, as the feeble expression of an infant science. It passes through the unfulfilled ambition of a Meteorological Society of London expressed in its transactions published in 1839 by John Ruskin, who defended the science as of universal interest and as necessarily dependent on universal co-operation, and then through the co-operative investigation of weather at sea, by which the tropical hurricane earned the name of 'cyclone' from Henry Piddington and riveted the idea of a travelling vortex on the science.

Co-operation in the study of weather at sea found further expression in the International Conference at Brussels in 1853, suggested by Lieut. M. F. Maury of the U.S. Navy, and the consequent formation of the Meteorological Department of the Board of Trade under Admiral FitzRoy in 1854.

About the same time, co-operation was extended to the collection of simultaneous observations from different stations by the aid of the electric telegraph. It began with some spasmodic efforts in 1851, and gradually developed until the weather-map in its present form, with the aid of wireless, is the most striking example of successful international co-operation.

Within each twenty-four hours the British Meteorological Office collects some seven thousand facts about the weather based on simultaneous observations at some hundred stations in Europe, Africa, Asia, the eastern Atlantic, its ships and its islands, in Greenland, Iceland and Spitsbergen, and the islands of the far north. The observations at the surface are supplemented by incidental observations of clouds and winds in the upper air, and occasional observations of pressure and temperature there too. Four hours of observation are chosen, and between the observing hours of 7 h. and 13 h. the observations for the twenty-four hours are transcribed, charted, printed, and posted with the inferences drawn from them about the weather to come.

For land-stations co-operation took the form of compiling observations of the meteorological elements as an expression of climate under the guidance of the British Meteorological Society from 1850, the Scottish Society from 1856, and the British Rainfall Organization from 1858. From the very beginning of regular observations the chronological sequence was used to identify the rhythm of the sequence of weather at individual stations as diurnal and seasonal. The temptation to seek for evidence of other rhythmic periods, especially those of the moon, was irresistible. It was ultimately guided into the righteous paths of harmonic analysis and the periodogram, which form an interesting chapter in the scientific history of the century.

Correlation came later when Galton had become disappointed with the behaviour of the cyclone and anticyclone. Francis Galton, who was one of the general secretaries of the British Association, had a great share in the development of the science of meteorology. He was actively interested in the establishment of a weather-map and also in the Kew Observatory in the Old Deer Park at Richmond, which was maintained by the British Association, and among other things he developed methods of recording automatically the variation of the meteorological elements.

When FitzRoy used his weather-maps to make public forecasts of weather and issue storm-warnings some prominent scientific authorities thought it premature, and on FitzRoy's death, at the request of the Government, a Meteorological Committee was appointed by the Royal Society to take on the work of the Meteorological Department of the Board of Trade and bring it into co-operation with the meteorological work of the British Association's Observatory at Richmond.

During twelve years a strenuous effort was made, chiefly under Galton's guidance, to use the records of the instruments at seven observatories like Kew to interpret the sequence of weather shown on the daily maps. Meanwhile forecasts were suspended. For twelve years every curve drawn by the instruments was reproduced with the associated maps for public information. The systems of closed isobars, now known as the cyclonic depression and the anticyclone, were the most striking features of the sea-level maps. The track and behaviour of every one of them during the twelve years was "set in a notebook learned and conned by rote". They were enthroned as Nature's proctors for the guidance of weather, and under their guidance forecasting was restored in 1879 by direction of those who had been critical in 1865.

The method of forecasting on the basis of cyclones and anticyclones was set out effectively by the Hon. Ralph Abercromby. The problem of the sequence of weather seemed to be solved. It was supposed that the progress of storms across the Atlantic could certainly be anticipated. Further investigation of the upper air by shell-bursts, by balloons, by the study of clouds under a new directing council, would clear up all the outstanding difficulties.

Somehow the effort failed. The maps used were bounded on the west by the Irish coast. Cyclones and anticyclones suggested rules of behaviour but did not keep to them, and a magnificent effort was made to find out the how and why of the irregularities by maps of the Atlantic and adjacent continents for the days of the year of polar exploration 1882–83; but no one has ever been able to make out a rational account of the behaviour of cyclonic depressions. The Norwegian school has traced with marked success the influence of the movement of the different kinds of air of which they are composed, but the origin of the currents of which they are composed is not yet understood. Disappointed, the council turned its attention to harmonic analysis of hourly values as a method of discovering the latent causes of weather, and Galton transferred his interest to eugenics.
